them worked were really almost pathetic. The surgeons and physicians were struggling to make the best of a bad machine. These children's hospitals ought to be got out into the country. Little hospitals, with five or six beds, supervised by men who knew how to treat crippled children, should be started in the country, where the sun would get fair play. In England the cause had no better friends at present than the Minister of Health and the Minister of Education, not because of agitation, but because a good example had been set by voluntary effort. When the country hospitals were established in the Free State it would be possible to set up small after-care centres. In an address in the National Children's Hospital Sir Robert Jones said that in visiting a hospital like that, which had for long held a high reputation, it was sad to see the work being carried on in drab surroundings. The fact that there were from 12,000 to 14,000 attendances a year showed the tremendous amount of work being done. During investigations made many years ago he had found that out of a thousand cases of rickets 95 per cent. were due to mothers not suckling their babies. In twenty-two counties in England where sunlight hospitals had been tried it was found that sunlight and fresh air had been the salvation of the cripples. It was not necessary to go abroad to get sunshine, as with the ultra-violet rays cases could be treated during the winter months. Sir William de Courcy Wheeler, in proposing a vote of thanks to the lecturer, mentioned that three-fourths of the hospital's patients were cripples or potential cripples. It was melancholy to think that, although they did their best, it was almost impossible in the present conditions to carry on effective work with the hospital situated as it was. It had been resolved unanimously to move the hospital from Harcourt Street at the first opportunity. The Government in Ireland, he said, was thoroughly sympathetic with that voluntary movement; but the State could not be expected to do anything until the volunteers showed the way. Then the State would come to their assistance. Cappagh had set a good example, and was probably the best modern open-air hospital. The Governor-General, who presided, said that in coming to Dublin Sir Robert Jones had performed a noble act of charity. The intention to move to the country was one that would attract widespread attention. The motion was passed with acclamation. In proposing a vote of thanks to the Governor-General, Sir William Taylor said, with regard to the removal of that hospital to the country, that he felt the need for the amalgamation of another hospital doing similar orthopaedic work in the city. The move could not be made without money, and amalgamation with another hospital that dealt with crippled children on similar lines would encourage the public to help.

#### ULSTER MEDICAL SOCIETY.

At the second meeting for the session of the Ulster Medical Society, on November 4th, the President, Dr. M. J. Nolan, read his opening address on "Insanity: its protean aspects in relation to bodily disease." Dr. Nolan said that in his early days he had had experience of general practice which had been of great value to him when he became an alienist; it showed him the many relations between insanity and bodily disease, and how the two departments were constantly coming into contact with each other; in 159 consecutive admissions to the Down District Asylum nearly every one required some physical attention. The experience also pointed to the principle that an asylum was a hospital to treat body and mind. No scientific definition of insanity had been generally accepted, but, for himself, he had adopted that of Mercier in 1890, which was that insanity is a disorder of the process of adaptation of the individual to his surroundings; psycho-pathology must give, not merely a description, but an explanation of the bases of mental disorder. Dr. Nolan then showed some charts of the physical causes of insanity, as given on admission by patients, and pointed out that there were more contributory than primarily causative factors. The most frequent was heredity; it did not produce insanity, but a neuropathic tendency might lead in many directions—for example, to tubercle, exophthalmic goitre, as well as to insanity. The head of the sperm cell, with all its inherent

potentialities, was the greatest marvel in creation. Preventive measures in the propagation of the unfit dealt with the parents, and did not remove atavistic recurrences in apparently healthy parents. Prolonged mental stress, tubercle, alcoholism, syphilis, heart disease and cardiovascular affections, sexual excess, the practice of contraception, the climacteric, sexual deprivation, were then described in order and their relative importance considered; numerous illustrative cases were related, especially that of an alcoholic father and a weak-nerved mother, who had eight children, many of whom suffered from Friedreich's disease, while the others were more or less weak-minded. The duty of the alienist was to get as full a knowledge of the patient, body and mind, as possible; thus only would he discharge his duty to the patient and to the public. Some important principles of treatment were emphasized, and the evils that might be caused by psycho-analysis carried out by those not properly equipped and trained were mentioned. Colonel Dawson proposed a hearty vote of thanks to the President for his address, and congratulated him on the large and liberal views expressed; this was seconded by Dr. Calwell, and passed with acclamation.

#### TUBERCULOSIS MORTALITY IN DUBLIN.

Mortality from tuberculosis has been reduced considerably in recent years in Dublin. Earlier diagnosis, better treatment, and greater care exercised by the patients to prevent infection have contributed to this condition. The very high death rate, however, is sufficient to impress the necessity for still greater effort to stamp out the scourge. In Dublin the mortality from tuberculosis in the past ten years has shown a great decrease (more than 50 per cent.), as the following table shows:

| All forms. Pulmonary. |                 | All forms. Pulmonary. |             |
|-----------------------|-----------------|-----------------------|-------------|
| 1916 ...              | 1,390 ... 1,065 | 1921 ...              | 749 ... 583 |
| 1917 ...              | 1,371 ... 1,058 | 1922 ...              | 738 ... 574 |
| 1918 ...              | 1,163 ... 896   | 1923 ...              | 686 ... 507 |
| 1919 ...              | 999 ... 738     | 1924 ...              | 623 ... 505 |
| 1920 ...              | 820 ... 615     | 1925 ...              | 664 ... 515 |

The present scheme for the treatment of tuberculosis in the county borough of Dublin only commenced in 1913. The number of cases occupying (with family) one, two, or three or more rooms was: one room, 746; two rooms, 319; three rooms or more, 229. This shows the effect of bad housing on the spread of the disease. Notifications of the disease decreased between 1916 and 1923, but in 1924 and 1925 there were sharp increases. The figures were:

|          |     |          |     |          |     |
|----------|-----|----------|-----|----------|-----|
| 1916 ... | 750 | 1920 ... | 583 | 1923 ... | 505 |
| 1917 ... | 761 | 1921 ... | 527 | 1924 ... | 701 |
| 1918 ... | 814 | 1922 ... | 511 | 1925 ... | 690 |
| 1919 ... | 734 |          |     |          |     |

It is well known that among the poorer class and in congested areas the disease is more prevalent than in the outlying districts, and this is clearly demonstrated by the figures for last year, which show 1.45 deaths per 1,000 in the urban districts, compared with 1.98 in the city. Portions of the north side of the city are, and have always been, the most generally affected.

## Correspondence.

### A MEDICAL ASPECT OF MINERS' SHORTER HOURS.

Sir,—In addition to wages and hours there is another factor in connexion with the strike which seems to have been overlooked: I refer to the human factor, as one which cannot but be of great interest from the medical point of view.

Under the nine-hour day the miners worked steadily and quietly, and always had a reserve of power wherewith to make, if necessary, an occasional spurt: under the eight-hour day that reserve was reduced considerably, whilst under the seven-hour day not only was there no reserve, but at the end of the shift the men (and I refer to the good workers) were exhausted.

Previously the men used to partake of food when underground, but under the seven-hour day they worked the

whole stretch without any stop for food. Even had they stopped, the pace at which they had to work was such that their digestions were likely to suffer. Conditions such as these are not calculated to improve the physical or mental health of the men; in fact, the reverse is the case, as is evidenced by the smallness of the number of colliers at work over 50, compared with the large number of those over 60 who used to carry on under the old conditions.

The men, when they reach the age of about 50, look out for day-work as they cannot stand the strain of piece-work, and, as far as I can gather, this is due to their hearts being more or less seriously disturbed.

That workers in the prime of life and full of working experience should be obliged to give up is a matter of great national and economic importance, and should be properly investigated. Collected data showing whether or no there is an increase of heart trouble in colliers, and more particularly in those over 50, during the last ten years would be invaluable. Personally my experience is that colliers' hearts are not so good as they used to be, owing to the speed at which they work. It would also be interesting to know if this pace has something to do with the greater nervous upset of the men, as shown, for example, by the increasing number of cases of nystagmus which are brought into court for compensation.

The method of working the coal has altered during the last few years. Formerly a man of 50 (or more) and his son used to work a "heading" together on their own; but to-day a large number of men at the facings work on the conveyer system, and pool their earnings, with the result that the young men are always gibling at their elders because the latter cannot keep up the speed. Under the old system a man could miss a day and make up by a little extra speed on the other days of that week. Under the seven-hour day there is no chance of making up, and consequently no opportunities for getting days off.

All these things have an important bearing on this national industry, and whatever there is of truth in connexion with them should be brought to light, apart altogether from the political aspect of the matter. —I am, etc.,

Swansea, Nov. 2nd.

G. ARBOUR STEPHENS.

### GOOD AND BAD DIETS.

Sir,—As one interested in the diet of children I would like to express my appreciation of Dr. Harry Campbell's letter (October 30th, p. 808). It is very true, as he points out, that we owe a considerable debt to physiologists like Colonel McCarrison for putting the various diet deficiency diseases on a scientific basis. At the same time it must be realized that all their findings boil down to the fact that these diseases are caused by unnatural diet and unnatural circumstances—that is, diet and conditions entirely different from those in which the animal evolved. The experience of zoological gardens bears this out, and it is a fact that the less it is possible to feed an animal or bird in captivity on its natural food, the less will be its chance of survival for any length of time. Another fact that emerges from both animal experiments and the experience of zoological gardens is that the young animal and bird are much more susceptible to an unnatural diet than adults.

The diet on which man evolved is largely a matter of surmise. My own view is that he was very largely carnivorous and lived on the flesh of the beasts he hunted, the birds he trapped, and the fish that he caught, eked out when times were bad with fruit berries, roots, and the like. What, then, was the diet of the pre-agricultural baby? At first breast-fed; as soon as it became mobile this must have been supplemented by the food of its parents, like the young of any mammal in its natural state. The infantile instinct of "putting things into the mouth" is deeply rooted, and no great stretch of imagination is required to picture the Neanderthal baby sitting at the mouth of its parents' cave sucking the meat off a horse-bone.

How far nowadays is the average well-to-do infant's diet from this, the natural one? I do not refer to those homes in which there are economic difficulties. It may or may

not be breast-fed for a few months. Bottles are then started of prepared cow's milk, with some highly manufactured carbohydrate patent food. At 10 months of age it gets white bread sop, rusks and biscuits added, and at a year vegetables put through a sieve. If lucky, it may get, soon after this, finely minced meat, though this advance is often delayed or a patent preparation of nuts substituted. The shelves of any modern nursery groan with tins of patent malted foods, pre-digested cocoa, patent rusks, patent preparations purporting to contain eggs in a highly digestible form, and curious substitutes for porridge; and the medicine cupboard is laden with bottles of syrup of figs, liquid paraffin, cough mixtures, and the like.

The results are often deplorable, and the physique of many children, whose parents want for nothing, is a disaster. They are nervous, suffer from obscure diseases, attributed to teething, and enlarged tonsils and adenoids are the rule rather than the exception. The remedy is to get back to nature, and as near as possible to the diet on which man has evolved from the ape. Let the baby be breast-fed till it no longer needs it. If this is really impossible the only adequate substitute is fresh Grade A cow's milk diluted suitably. Teach the infant to eat and drink from a cup, not a bottle, as early as possible, and supplement the breast milk with natural foods—fresh meat, fresh fish, fresh eggs, and fresh vegetables and fruit, without prepared or patent foods of any kind. A healthy breast-fed baby will take all the above-mentioned articles of diet well at 7 months of age, and by the time it is 10 months will be able to take all ordinary articles of diet and need only half a pint of milk a day. This is a fact that I have proved many times, and the results are infinitely better than by the older method.—I am, etc.,

Clifton, Bristol, Nov. 6th.

RICHARD C. CLARKE.

Sm,—Dr. Harry Campbell suggests that "we can reach an even deeper level of truth concerning human dietetics by studying the diet of the pre-agriculturists" than by studying the diet of comparatively primitive agricultural peoples. In the sacred legends of the natives with whom I am best acquainted—the New Zealand Maori—the cultivators are regarded as improved man, and the hunters as unimproved man. Man is said to be an improved monkey, and the monkeys are termed "ancestral peoples." The diet of these ancestral peoples consists of the "wild" foods of vegetable origin; the diet of the hunters (the pre-agriculturists) consists of "wild" foods of animal and vegetable origin. In Maori philosophy cultivation was beneficial; conquest was deleterious—fatal ultimately to the conquerors. These who could not cultivate the dietetic means of life ultimately lost life itself.

If we take the four races of mankind—the black, the yellow, the brown, and the white—we find that the blacks have mostly remained in Africa; the yellows have mostly remained in Asia; the whites are mostly in Europe, and in recent times in America and Australasia; but the browns have increased and multiplied all over the earth, they form what Huxley termed a "belt of dark-whites." The founders of the British Empire went to so-called new countries, but these new countries had previously been discovered by the dark-whites, and cultivated to a greater or less extent by them.

The diet of these dark-whites consisted mainly of vegetable foods, with fish and bird. These vegetable foods were mainly the aroid roots, sweet potatoes, fern-root, cassava, etc., all of which were grown in terrace, pit, and surface cultivation; with sow-thistle, fern-shoots, etc., used as we use spinach; various fruits and nuts were also eaten. Vegetables as well as fish and bird were smoked and dried. From the Americas across to New Zealand the cereal was maize, roasted and ground, boiled, and sometimes germinated and then cooked. The cooking was a prolonged process of steam-roasting in the ground ovens, and foods—such as bitter cassava—which were unwholesome or poisonous raw were by cooking rendered palatable and nutritious. Purgative leaves or herbs were cooked with binding foods; or sacred earth (ashes or sand) was added.

The sacred legends taught that the bowels were the seat

of health, and that evacuation must occur two or three times a day; otherwise "the inner man" was regarded as out of order. The remedy then was rest from food and the taking of herbal beer (made from the sow-thistle), with exercises specially designed to facilitate evacuation. It is true that the peoples holding these views of life appear to have been "conquered" by the white race, but history and pre-history appear to reveal a succession of such conquerors, with the brown peoples or dark-whites ultimately again in possession in the long slow course of the ages, because the white race can conquer and exploit, but apparently cannot yet create and cultivate, and so ultimately it perishes of the so-called diseases of civilization. Our contact with the native races appears at first to be fatal to them. If they fail to be benefited by our superior accumulations of knowledge doubtless they deserve to perish. But, if we fail to be benefited by their superior wisdom in cultivation, we cannot survive—excepting in the sense that the ancient Greeks and the ancient Romans are still here.—I am, etc.,

ETTIE A. ROUT

(Mrs. F. A. Hornibrook).

London, W.1, Oct. 3rd.

#### THE DEVELOPMENT OF VAGINAL OPERATIONS FOR GENITAL PROLAPSE.

Sm,—I desire to thank Dr. R. H. Paramore for his courteous and thoughtful reply on August 21st (p. 360) to my letter in your issue of August 7th (p. 274), and to tell him that I read both reviews of his volumes of *Statics* when they appeared in the *Medical Journal of Australia*, as well as the volumes themselves, and was struck by the ability with which the subject was presented. It is therefore with much regret that I find myself unable to agree with the statement that the cardinal ligaments, "from their structure—in virtue of their non-striped muscle content—are not capable of sustaining the pressure which during life is continuously tending to depress the uterus." On the contrary, it is in virtue of this very fact, their non-striped muscle content, that they are the main supports of the uterus; and this view is emphatically borne out by Professor A. F. Dixon, as mentioned in my previous letter.

Your other contributor, Dr. J. W. Bride (August 21st, p. 361), cites the work of Cameron and Derry, quoting vaguely from Elliot Smith's article in the *Journal of Anatomy and Physiology* (April and June, 1908). But their work refers only to the pelvic fascia and says nothing whatever about the all-important muscle bundles, which radiate laterally outwards from the neck of the uterus and form the "non-striped muscle content" above referred to. So that, as far as the origin, structure, and functions of the cardinal ligaments are concerned, the work of Cameron and Derry is valueless. Professor Elliot Smith points out that his own work "deals mainly" with the pelvic fascia and the mesodermal sheaths of the pelvic blood vessels and viscera in the male.

Dr. Bride objects to the term "ligament" as applied to the structures under discussion. Perhaps they are not ligaments in the strictly anatomical sense. Neither are the infundibulo-pelvic, the utero-sacral, even the broad "ligaments" themselves, and quite a number of others in human anatomy, but the term is found useful and convenient by the operating surgeon and is justified by custom.

In the paper read by Dr. Fothergill before the Obstetric Section of the Royal Society of Medicine in December, 1907, to which attention is significantly directed, it is stated that the support of the uterus "is accomplished by the fibrous sheaths of the blood vessels and accompanying structures which supply the uterus." In closing the discussion, however, the President of the Section, Dr. Herbert Spencer, with his usual acumen, said that "anyone who had performed a total abdominal hysterectomy . . . would find it difficult to accept the statement that it was the sheaths of the vessels that kept the uterus in place." Probably the same difficulty will present itself to most of your readers.

In conclusion, it remains to be added that, from the facts adduced in this and my previous letter, it may be justly

claimed that the first accurate description of the anatomy of the cardinal ligaments was published by the late Arthur Nyulasy in 1914.—I am, etc.,

FRANK A. NYULASY, M.D.

Melbourne, Australia, Sept. 5th.

#### LEAD AS AN ABORTIFACIENT.

SIR,—Some time ago, in country practice, I had a message from a neighbour asking me to see with him a case of acute abdominal disease. The history was this: A robust young woman (married three months) had had pain in the stomach a few days previously, and again on the day before, when she was first seen. On inquiry her doctor was informed that she was regular every month. Next day she was fairly well till after tea, when she had agonizing pain and urgent vomiting, which continued till I arrived, about four hours later. Nothing definite was made out till rectal examination revealed an enlarged uterus; on vaginal examination it corresponded to a three months' pregnancy, and the state of the breasts confirmed this. Thinking it strange that she had been misleading everyone, I looked at her gums and found a blue line. Morphine followed by a course of mistura alba was successful. She went to full time without any bad result. She never revealed the truth.

Some years after, in London, I had another case, which may be summed up thus: (1) Colic and vomiting; headache, albuminuria, constipation; (2) blue line on gums; (3) anaemia slight, yet films showed brisk pathological regeneration culminating in punctated erythroblasts and leucoblasts. Such a film is pathognomonic of lead poisoning, and the woman (married with three children) admitted that she had taken lead lotion because she had missed her period. She was very ill for some days, requiring morphine on several occasions. After a few weeks on mistura alba she was quite well. Three months from the beginning of her illness the conspicuous blue line had quite disappeared, the blood film was normal, albuminuria had gone, and pregnancy was well advanced. A small but healthy girl was born six and a half calendar months from the beginning of the illness. As the woman gave every information, I found that she had taken 60 grains of lead acetate in a fortnight.

This case proves that even marked blue lines may disappear within three months of treatment. In a series of cases in 1922 (*BRITISH MEDICAL JOURNAL*, January 20th, 1923, p. 103) I found that in about three months blood films became normal and lead disappeared from the urine. In recent cases, therefore, all three disappear together.—I am, etc.,

Ealing, W.13, Oct. 25th.

ROBERT CRAIK.

#### CLOTHING AND CATARRHS.

SIR,—In the *Daily Express* of November 1st is an article, announced as one of a series by famous physicians, on "Why have a cold?" by Dr. Leonard Williams.

He advocates the avoidance of excessive warm clothing, and I am not concerned with this contention. What interests me is the remarkable hypothesis which he uses to support it. He considers that the respiratory function of the skin is impeded by too much clothing, thereby throwing so much more work on the lungs and "air passages" that they soon "tire" and become liable to microbial infection.

Dr. Williams must be aware that the respiratory function of the skin in man is so small as to be almost negligible. Next there is no reason to suppose that increased respiration by the lungs lowers their resistance—or why do we advise people to take exercise? Lastly, the respiratory function of the skin is undoubtedly increased by hyperaemia and sweating, while ordinary clothes freely permit the interchange of gases so that its respiratory function, such as it is, is presumably increased by warm clothing.

I can only conclude that this hypothesis was introduced to give a scientific flavour to the article, and that it is not one which Dr. Williams would be prepared to maintain seriously amongst medical men, and this is my reason for writing this letter.

In the same newspaper there have recently been articles

by eminent men of science on such difficult subjects as relativity and the structure of the atom. All the writers have shown the utmost care to preserve accuracy of statement in a popular article, and to me the contrast with this sort of thing is most unpleasant.

I think for the credit of our profession that those who are now taking to medical journalism should endeavour to act up to the popular idea that they are also scientific men.—I am, etc.,

Dover, Nov. 3rd.

A. R. JORDAN, M.D., F.R.C.S.

#### MEDICAL PRIVILEGE IN THE COURTS.

SIR,—I was interested in the letter of Dr. L. A. Parry on "Medical privilege in the courts," published in the *JOURNAL* of October 9th (p. 665). I note that Lord Mansfield stated, "If a surgeon was voluntarily to reveal these secrets, to be sure he would be guilty of a breach of honour, and of great indiscretion." The secrets referred to are secrets of a patient entrusted to the medical man by virtue of his position as professional attendant.

I take this opportunity of stating that about two years ago I was called professionally to attend a woman who had been stabbed in the thigh by her husband a few days previously. The wound was healing excellently owing to the very able treatment given by the assailant, an ex-R.A.M.C. man. There was no danger whatever to life. I told the wife that she would be well advised to inform the police, her husband being present on the occasion. The wife indignantly refused to do so, telling me that she had forgiven her husband, and added that if he should go to prison she would lose the advantage of a pension that he was receiving. Consequently I let the matter rest. Ten days later the husband once again assaulted the woman, and the police were notified and the previous assault was mentioned.

The man was tried at Lewes Assizes in December, 1924. I was subpoenaed and gave evidence. The judge, Mr. Justice Swift, asked me to give my reason for not having informed the police of the original offence. I answered, "I did not and do not consider that I was under any legal obligation to do so." Mr. Justice Swift, with anger, replied, "No, it was not your legal obligation, but it was your moral obligation, and I consider it was most regrettable that you did not inform the police. It is the duty of every good citizen to inform the police when he becomes aware that a crime has been committed."

I should be glad to know if the learned judge was correct in his observations.—I am, etc.,

Brighton, Oct. 9th.

W. E. LEVINSON.

#### "RISING OF THE LIGHTS."

SIR,—With reference to the term "rising of the lights" given as a cause of death in the Bills of Mortality quoted in the article ("Nova et Vetera") in your issue of October 9th, and the suggestion that this may refer to emphysema, the following passages, quoted from *Domestic Medicine, or a Treatise on the Prevention and Cure of Diseases*, by William Buchan, M.D., Fellow of the Royal College of Physicians, Edinburgh, printed in London, 1798, are of interest.

##### "OF THE CROUP."

"Children are often seized very suddenly with this disease, which, if not quickly relieved, proves mortal. It is known by various names in different parts of Britain. On the east coast of Scotland it is called the croup. On the west they call it the croup or stuffing. In some parts of England, where I have observed it, the good women call it *rising of the lights*. It seems to be a species of asthma attended with very acute and violent catarrhal symptoms.

"It is attended with a frequent pulse, quick and laborious breathing, which is performed with a peculiar kind of croaking noise, which may be heard at a considerable distance. The voice is sharp and shrill, and the face is generally much flushed, though sometimes it is of a livid colour. . . .

"Dr. William Turnbull, in London, a physician of great experience, observes that he never found blistering of any service; but recommends cataplasms of garlic, camphor, and Venice treacle, to be applied both to the throat and soles of the feet."

NOV. 13, 1926]

It would appear, then, that this complaint, with its high mortality, was diphtheria. It is not stated whether Dr. Turnbull's application to the soles of the feet was intended to draw the lights down again!—I am, etc.,

P. P. DALTON.

London, N.W.5, Oct. 30th.

## THE PREVENTION OF SCARLATINAL NEPHRITIS.

Sir,—In the excellent summary of my address to the Ulster Medical Society on "The constitutional factor in disease," which appears in your issue of November 6th (p. 853), the names of the authorities I quoted in support of my views are omitted by the reporter. I am anxious to draw attention to the fact that the underlying diathesis which predisposes to acute nephritis, and the means I described whereby this serious complication can be completely prevented in scarlet fever, are the discovery of Dr. A. A. Osman. His work, which constitutes what I believe to be one of the most important advances in public health of recent years, is still unpublished, but he has briefly summarized in it a paper which will appear in the forthcoming October number of the *Guy's Hospital Reports*.—I am, etc.,

ARTHUR F. HURST.

New Lodge Clinic, Berks, Nov. 7th.

## Medico-Legal.

### TWO MEDICAL MEN CHARGED WITH CRIMINAL ABORTION.

The preliminary magisterial hearing of the case against Dr. Arthur Stuart Holden of Preston, and Dr. Frederick Langton Webster of Bamber Bridge, near Preston, on charges of feloniously causing the death of Miss Norah Marmion, aged 24, the daughter of a Penmaenmawr quarry owner, at Bamber Bridge on October 7th, while performing an illegal operation, and on other charges of using an instrument and of conspiring together with the dead woman for the alleged purpose, commenced before the Bamber Bridge justices on November 5th and 8th. It was announced that the charges of aiding and abetting which had been preferred against Major W. Blackburne and Mrs. Blackburne, which Mrs. Holden would be withdrawn.

The proceedings at the inquest on the deceased woman, which terminated in the two doctors being committed for trial at the next Manchester Assizes on a charge of murder, the other three accused persons being committed as accessories, were briefly reported in the last issue of the *BRITISH MEDICAL JOURNAL*, at page 860.

#### Case for the Prosecution.

Mr. Laski, counsel for the Crown, in his opening statement, said that prior to this unfortunate occurrence, the deceased woman was taken out a good deal by a Mr. Alexander French of Waterloo and a Mr. James Allman of Great Crosby, the latter of whom went abroad some months ago. The deceased woman was engaged to be married to a doctor from July, 1925, to July, 1926. It would be given in evidence that she had intimacy with both Mr. French and Mr. Allman. On September 1st, 1926, she visited her sister, Mrs. Blackburne, at Preston. During the visit she met Mr. French and informed him of her condition, and, in consequence, he offered to marry her, but she refused him. On October 5th the deceased woman called at Dr. Holden's surgery, and on October 8th she went with Dr. Webster, Dr. and Mrs. Holden, and Major and Mrs. Blackburne to the theatre, and afterwards on to Dr. and Mrs. Holden's house for refreshment. The following evening a visit was paid to Dr. Webster's house ostensibly to play bridge, but, in the view of the prosecution, an illegal operation was performed by one of the doctors, Miss Marmion dying from shock.

Evidence was then called. Mr. Peter Marmion, the deceased's father, said he did not at the time think there was anything unusual about his daughter's visit to her sister.

Mr. Alexander French, aged 23, employed by a firm of sanitary engineers at Liverpool, said he first became acquainted with Miss Marmion when living at Waterloo about five or six years ago. He took her about a great deal, but he had never been engaged to her. He saw her twice on her last visit to Preston, the last occasion being when he saw her off at the station on October 4th. He also saw her at Southport two days earlier, when she offered to marry him, but she refused him. She did not allege that he was the cause of her condition, although, in fact, there had been intimacy between them. He first heard of her death on

## MEDICO-LEGAL.

the morning of October 8th, when Major Blackburne informed him over the telephone. He then went to Preston, saw Major Blackburne, and asked what had happened. Major Blackburne replied: "It's very terrible. All I can say now is that Norah died last night." When he saw Mrs. Blackburne earlier she said that Norah had died, but that she did not really know what had happened, adding, in reply to his questions, that that was the first she had heard of her sister's condition.

#### The Conspiracy Charge.

An objection by Mr. G. Ambler, solicitor, who appeared for Major Blackburne, against the admission of evidence of events prior to Miss Marmion's death was recorded by the court, but counsel pointed out that there was a charge of conspiracy against two of the defendants.

Mrs. Elizabeth Rome of The Grange, Euxton, said on October 7th she lunched with Mrs. Blackburne and Miss Marmion at Major Blackburne's residence, and later had tea with Major Blackburne and her own husband, she and her husband leaving at 5.45 p.m.

A further objection to a question tending to elicit what Miss Marmion said in the presence of Mrs. Rome and Mrs. Blackburne as to what she was going to do that night was recorded by the court, though it was allowed, counsel again pointing out that the answer formed part of the case of alleged conspiracy of the two doctors with Miss Marmion. Mrs. Rome then stated that what Miss Marmion said was that she was going that evening to play bridge at Dr. Webster's, and that Dr. and Mrs. Holden and Major and Mrs. Blackburne were going too.

#### Dr. Holden's Alleged Statement.

Police-Inspector Blenkinsop of Bamber Bridge said Dr. Holden came to his house at 1.45 a.m. on October 8th, and informed him of Miss Marmion's death at Dr. Webster's house under an anaesthetic during an operation. Dr. Holden also said that the girl was expecting to become a mother. Following a remark by the witness, Dr. Holden replied: "I have let Dr. Webster in. She was my patient."

Cross-examined by Mr. Lustgarten, for Dr. Holden, the witness said after his interview with Dr. Holden he wrote on a slate: "Staying temporarily with Dr. Holden. I have let Dr. Webster in. She was my patient," and other matters. He had allowed the writing to be rubbed off the slate since.

Questions were put to this witness tending to show that his evidence was unreliable, and, later, Detective-Inspector Fenton of the Lancashire Constabulary admitted, in cross-examination, that the police-inspector was not suffering from worry alone, but should not be required to answer the question whether Inspector Blenkinsop had attempted to commit suicide. Inspector Fenton further said that when he arrested the accused doctors, Dr. Holden and Dr. Webster replied that they were not guilty of the charge of causing Miss Marmion's death by an illegal operation. When further jointly charged with the offence, and also with conspiring with the deceased in its commission, each denied his guilt.

#### The Medical Evidence.

Dr. W. A. Simpson of Bamber Bridge, acting police surgeon, who conducted the *post-mortem* examination on October 9th in the presence of both accused and four other doctors, gave his findings in detail. He came to the conclusion that death was probably due to asphyxia following the administration of an anaesthetic acting on a fatty heart. He found circumstances which led him to think that an instrument had been used, but he did not find any sign of an instrument having been used. He based his opinion as to the cause of death on the statement said to have been made to Police-Inspector Blenkinsop by the two accused doctors that an anaesthetic had been used. Cross-examined, the witness said his examination of the uterus did not go far enough to enable him to tell definitely whether or not the deceased woman was pregnant.

Dr. K. M. Duncan of Preston, senior police surgeon for Lancashire, who also was present at the *post-mortem*, concurred with the findings of the previous witness, he said, he found difficult to give actual cause of death, which, he said, he found difficult to give with any certainty. He did not think it sufficiently evident that there had been asphyxia, and thought the condition of the body more consistent with death from shock. He detected no trace of an anaesthetic.

Sir Bernard Spilsbury detailed the results of his examination of organs sent him. His definite opinion was that death was due to shock consequent upon the passing of an instrument used for an anaesthetic, and he would have expected to detect an odour. There was evidence that artificial respiration efforts had been made, and he would not expect to find this under ordinary conditions at some time after death. The stomach was dilated and empty, and he would not expect to find this under ordinary conditions at the time when the woman died—which he put at between 9 and 10 p.m. He also came to the conclusion that an ovum was removed from the body after death. It was customary, he believed had taken place. Cross-examined, Sir Bernard Spilsbury said, in his opinion, death occurred certainly within five minutes of the passing of the instrument. Before examining the organs he had received a copy of Police-Inspector Blenkinsop's statement.

The accused medical practitioners pleaded not guilty, reserved their defences, and were committed for trial at the next Manchester Assizes. Bail was refused.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

PARLIAMENT reassembled on November 9th, and the House of Commons commenced the Report stage of the Electricity Bill, which was expected to last most of the week. Replying to Mr. Clynes, Mr. Baldwin gave a long list of bills which the Government hopes to carry into law before the session ends. Among these were the Housing of Rural Workers Bill, Mental Deficiency Bill, Prisons (Scotland) Bill, London University Bill, Judicial Proceedings Bill, Lead Paint Bill, Legitimacy Bill, Smoke Abatement Bill, Coroners Amendment Bill, and Births and Deaths Registration Bill. The Prime Minister added that no progress would be attempted this session with the Factories Bill.

In the House of Lords on the same day the Earl of Plymouth, replying to Lord Astor, said the new Factories Bill did not give special measures of protection to juveniles between 14 and 18 years of age in occupations not at present regulated by Statute. He did not think the bill could be amended to include them. Legislation on the matter would be premature until the conditions and hours of labour of young persons employed in factories had been settled.

**University of London Site.**—In reply to a question by Sir W. Davidson as to grants promised to the University of London, the Chancellor of the Exchequer said that he had promised in June that the Government would be prepared, within certain financial limits, to ask Parliament to make provision for improved accommodation for the University of London, subject to the approval by the Treasury of plans to be formulated by the Senate. The offer was not limited to a South Kensington or a Bloomsbury site. [The action of the Senate is mentioned below.]

**Inspection of Dairy Farms.**—In reply to a question on November 9th, the Parliamentary Secretary to the Ministry of Health said that fresh legislation to amend the Milk and Dairies (Consolidation) Act, 1915, was not contemplated. The proposal that all medical officers in any urban district to which milk was supplied should have the right to inspect the farm from which such supplies came would therefore not at present be considered. In reply to another question, he said that the Ministry saw no reason for exempting from the requirements of the Order farmers who sold milk only to farm workers and their families.

### Notes in Brief.

The Secretary for India has recently sanctioned a scheme which will provide certain passage facilities for Indian officers of the Indian Medical Service who desire to study in this country.

In reply to a question as to the increase of imports of condensed machine-skimmed milk, Sir Kingsley Wood said that the regulations required every tin of such milk to be labelled "Machine-skimmed" and "Unfit for babies."

The question whether the addition of certain chemical substances to flour, with the object of modifying its baking properties, was objectionable on grounds of health and what restrictions, if any, should be placed on it, has been referred to a Departmental Committee.

## Universities and Colleges.

### UNIVERSITY OF LONDON.

DR. R. D. LAWRENCE has been appointed Lecturer in pathology at King's College and in Medical Statistics at the Faculties of Medicine and Science.

The University medal in Branch VI (Tropical Medicine) of the M.D. examination for internal and external students, July, 1926, has been awarded to Richard M. Morris, B.Sc., of the London Hospital and the London School of Tropical Medicine. A grant of £150 from the Thomas Smyth Hughes Fund has been made to Miss Kathleen Chevrast, B.Sc., to defray the cost of apparatus in connexion with her research on glycolysis in cerebro-spinal fluid.

The examinations will commence on April 19th and June 28th, 1927, for fourteen medical entrance scholarships and exhibitions of an aggregate value of £1,513 tenable in the Faculty of Medical Sciences of University and King's Colleges, and in the medical schools of King's College Hospital, University College Hospital, the London Hospital, and the London (Royal Free Hospital) School of Medicine for Women. Full particulars and entry forms may be obtained from the Secretary of the Board, Mr. S. C. Ranner, M.A., of the Medical School, King's College Hospital, Denmark Hill, S.E.5.

Subject to the consent of the Chancellor of the Exchequer to proposed definite negotiations with the Duke of Bedford for the purchase of part of the Bloomsbury site.

### UNIVERSITY OF CAMBRIDGE.

H. W. FLOREY, M.B. Adelaide, has been elected to an official Fellowship at Gonville and Caius College for his physiological researches. After graduating in medicine at the University of Adelaide in 1920 he entered Magdalen College, Oxford, as a Rhodes

Scholar. In 1924 he became a member of Caius College on election as John Lucas Walker student in pathology, and in 1925 he was elected to a Rockefeller Research Fellowship.

### UNIVERSITY OF BIRMINGHAM.

The Council of the University of Birmingham has decided to ask the Court to confer the title of Emeritus Professor on Professor O. J. Kauffmann, M.D., Joint Professor of Medicine in the University from 1913 to 1926.

Dr. T. L. Hardy, Assistant Physician to the General Hospital, has been appointed assistant to the chair of medicine; and Dr. C. C. W. Maguire, Physician for Out-patients at Queen's Hospital, has been appointed honorary demonstrator in the department of anatomy.

### NATIONAL UNIVERSITY OF IRELAND.

THE following degrees were conferred at a meeting held in University College, Cork, on November 2nd:

M.D.—M. Whelton.

M.Ch.—J. Kieley.

M.B., B.Ch., B.A.O.—J. F. Carr, E. Egan, Annie A. O'Connor, M. Ahern, A. Callaghan, T. F. Crowley, D. Duggan, D. McCarthy, D. F. McCarthy, J. L. MacSweeney, D. Mahony, F. D. Murphy, M. A. Neville, D. O'Connell, M. O'Donnell, J. O'Driscoll, D. J. O'Sullivan, E. T. O'Sullivan, J. M. Quinlan, T. Richardson, J. Roche, E. J. M. Scanlan, J. Scott.

D.P.H.—M. Harris-O'Connor, E. T. Callanan, W. J. O'Donovan.

### ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

A QUARTERLY meeting of the College was held on November 2nd, when the President, Dr. George M. Robertson, was in the chair.

Dr. L. S. P. Davidson and Dr. W. E. Foggie took their seats as Fellows of the College. Dr. R. G. Gordon (Bath), Dr. J. R. Drever (Edinburgh), Dr. A. L. S. Take, M.C. (Dunfermline), and Dr. J. F. Christie (Aberdeen) were elected Fellows of the College.

The Hill Pattison-Struthers bursaries in anatomy and physiology and in clinical medicine were awarded to H. G. Somerville and H. B. Martin respectively. The Wood bursary was awarded to J. P. Collie.

The licence of David William Anderson, which had been suspended on May 8th, 1925, was restored.

At an extraordinary meeting of the College held on the same date the licences of Ebadji Jamshedji Treasurvala, Bombay, and Kaikhushru Edalji Master, Bombay, were suspended *sine die*.

### ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

A meeting of the College was held on Friday, November 12th, at which the necessary business was transacted. The necessary business was transacted at the College: Shafik

## The Services.

### TERRITORIAL DECORATION.

The Territorial Decoration has been awarded to the following officers of the Royal Army Medical Corps, Territorial Army: Majors William Cooper Gunn, Robert Harvey, and Frederic Edwin Hubert Keogh.

### NO. 14 STATIONARY HOSPITAL.

The seventh annual dinner of the medical officers of No. 14 Stationary Hospital will be held on Friday, December 10th, at the Trocadero Restaurant, Piccadilly, at 7.45 p.m. Lieut.-Colonel J. R. Harper, C.B.E., will be in the chair. The price of the dinner will be 15s. (exclusive of wines). The honorary secretary is Dr. H. L. Tidy, 39, Devonshire Place, W.1.

### DEATHS IN THE SERVICES.

Lieut.-Colonel Thomas James Paul Holmes, R.A.M.C. (ret.), died at Hove on October 21st, aged 81. He was born on October 23rd, 1844, the son of the Rev. J. P. Holmes, rector of Gallen, King's County, and was educated at Trinity College, Dublin, where he graduated M.B. in 1866, taking also the L.R.C.S.I. in the same year. He entered the army as assistant surgeon on April 1st, 1867, attained the rank of brigade surgeon lieutenant-colonel on May 3rd, 1893, and retired on April 7th, 1897. After his retirement he was employed at Kingston from 1897 to 1902.

Major William Wallace Boyce, D.S.O., R.A.M.C., died suddenly in London on October 31st, aged 43. He was educated in Dublin in the school of the Royal College of Surgeons, and took the L.R.C.S.I. and L.R.C.P.I. in 1905. He entered the R.A.M.C. as Lieutenant on July 30th, 1906, and reached the rank of major on January 28th, 1919. He served throughout the recent great war, was thrice mentioned in dispatches, and received the D.S.O. on March 8th, 1919.

Captain George Cuthbert Robinson, R.A.M.C., died in a nursing home, from illness the result of active service, on October 18th, aged 33. He was born on December 21st, 1892, the son of Surgeon Lieut.-Colonel G. S. Robinson, Scots Guards, and was educated at St. Thomas's Hospital, taking the M.R.C.S. and L.R.C.P.Lond. in 1916. He joined the R.A.M.C. as a temporary lieutenant on February 8th, 1916, took a permanent commission from January 1st, 1917, became temporary captain, after a year's service, on February 8th, 1917, and was confirmed in that rank from August 8th, 1919. He served throughout the war from 1916 on.

# FRANCIS MITCHELL CAIRD.

## Obituary.

F. M. CAIRD, M.B., C.M., F.R.C.S.E., LL.D., Emeritus Professor of Clinical Surgery, Edinburgh University. We announced briefly in our last issue the death on November 1st, in Edinburgh, at the age of 73, of Emeritus Professor Francis Mitchell Caird. Although he had had a few signs of cardiac weakness while he was in full mental place with startling suddenness while he was in full mental and bodily activity. He was born in 1853, and was educated at the High School, and thereafter assisted the late Professor John Hutton Balfour in the Botanical Department of the University, and at a later stage adopted medicine as a career. He graduated M.B., C.M. at Edinburgh in 1877. As Lister had been professor of clinical surgery up to the preceding year, Caird came greatly under his influence, having served both as a dresser and clinical clerk in his wards. This to a great extent determined his career, for, having an ardent love for surgery, he began to devote himself to preparations for work as a surgeon almost immediately after graduation. In the summer session of 1878 he became resident in the surgical wards of Mr. Chiene. In 1879 he took the diploma of L.R.C.S. Edin., and proceeded to the Fellowship in 1880. Caird thus became the living transmitter of the Listerian doctrines and practice in Edinburgh, and these were well summed up in a pamphlet entitled *Hints on the Antiseptic Management of Wounds, "Listerism,"* which he published in 1880.

With the object of gaining a fuller knowledge of pathology and anatomy he went to the University of Strasbourg, where he studied especially under von Recklinghausen and Joessel. On his return to Edinburgh he was demonstrator in anatomy for some three years at Minto House and in Surgeons' Hall under Dr. (later Professor) Cossar Ewart and Mr. C. W. Cathcart. At the same time he was invited by Professor Chiene, who at that time was one of the ordinary surgeons to the Royal Infirmary, to become his private assistant. In this capacity he not only assisted Mr. Chiene in his private surgical practice, but helped him in the teaching of his large surgical class. This position he continued to hold until 1886; when Mr. Chiene was appointed professor of surgery in succession to Professor Spence, in the year 1882, Caird became the University assistant in the chair of surgery. In 1886 Mr. Caird was elected to the post of assistant surgeon to the Royal Infirmary of Edinburgh, and commenced to lecture on his own account in surgery as a recognized extra-mural teacher; for the next twenty years he continued to lecture with success on this subject, attracting large classes of students. He was distinguished for great clearness of exposition as well as forcefulness and brevity of expression, qualities which rendered him highly popular as a teacher. In 1900 he was appointed to full charge of wards in the Royal Infirmary, and here as a clinical teacher his popularity was even greater.

In 1908, following upon the death of Professor Annandale, he was elected to fill the Regius Chair of Clinical Surgery

in the University of Edinburgh, a post which he held till 1919, when he resigned and was succeeded by Sir Harold Stiles. On his retirement from this post he received, in 1920, the honorary degree of LL.D. from the University, and at the same time was elected by the managers of the Royal Infirmary a consulting surgeon to that institution.

At an early stage in his career Professor Caird had been greatly influenced by the work of some of the Continental surgeons, particularly of Professor Mikulicz of Breslau, and almost every summer he paid a visit to one or more of the great Continental medical schools, especially in Germany, where he came into personal contact with some of the eminent men by whom surgical science was being advanced. In this way he was one of the first to practise various operations in Scotland. Following his original master, Lister, he was an early upholder of the systematic use of rigorous aseptic methods. The early introduction of local and spinal anaesthesia in major operations at Edinburgh was also largely due to him. While still an assistant surgeon to the Royal Infirmary he had been greatly impressed by the advances taking place in German hospitals in regard to abdominal surgery. Billroth in Vienna had been the first, in 1881, to remove the pylorus successfully for cancer of the stomach, and during the years 1878 to 1883 had been a pioneer in performing a large number of intestinal resections and enterorrhaphies. Influenced by this work, Caird was performing gastric and intestinal operations at an earlier date and on a larger scale than any of his colleagues in Edinburgh. The results of this work were presented in various papers, published mainly in the *Scottish Medical and Surgical Journal*; among the subjects were operation for stricture of the large intestine (1901), enterectomy for tuberculous stricture of the intestine (1904), and operation for perforated gastric ulcer (1905). In 1906 he published in the *Medico-Chirurgical Society's Transactions* a series of cases of operation for perorated gastric and duodenal ulcer. He was also one of the earliest and most successful operators in the domain of excision of the rectum for carcinoma, and published a paper on the subject in 1903; his outstanding position in this department of surgery was recognized by his being invited in 1913 to deliver on it the William Banks Memorial Lecture at the University of Liverpool. Still another department of operative surgery in which he was a pioneer was excision of the tongue for cancer, and in 1911 he published a record of his work in the *Medico-Chirurgical Society's Transactions*.

Although Caird was recognized as possessing special ability and special interest in the domain of surgery of the alimentary tract, his opinion and his skill were no less valued by his colleagues in general surgery. In regard to the surgery of the limbs, he had published a valuable monograph on *The Shoulder Joint in Relation to Certain Dislocations and Fractures* as early as 1886. Professor Caird was joint author with Mr. C. W. Cathcart of *A Student's Atlas of Bones and Ligaments and A Surgical Handbook*, both of which have enjoyed a great measure of success. The latter especially found much favour with students, and has been the constant companion in practice of many general practitioners.

PROFESSOR F. M. CAIRD.

[A. Swan Watson, Edinburgh.

In 1901 Professor Caird received the Victoria Liston Jubilee Prize from the Royal College of Surgeons of Edinburgh "for the greatest benefit done to practical surgery by any Fellow or Licentiate of the College during the quadrennial period ending June 20th, 1901." In 1906 he delivered the annual address on surgery to the Canadian Medical Association at its meeting in Halifax. During the great war he acted as one of the consulting surgeons to the British Expeditionary Force in France, having the rank of colonel in the Army Medical Service and being attached to the Third Army. At the last meeting of the British Medical Association in Edinburgh he was joint secretary to the Surgical Section. His interest in the Association did not diminish, and in 1915-16 he was president of the Edinburgh Branch. He was secretary of the Medico-Chirurgical Society of Edinburgh for a considerable time, and at a later date occupied the presidential chair of this society; those who attended can remember the skill with which he conducted its meetings and the admirably brief and lucid manner in which he was wont at the close of a discussion to sum up the points of interest and importance contributed by various speakers.

To the end of his life Professor Caird preserved the quiet, alert, and kindly manner which had characterized him in his relations with many generations of pupils. He was a man of tender sympathy, and had in a high degree the ability of inspiring confidence and affection among his patients. His energy and the amount of daily work he could accomplish were extraordinary. By his students he was held both in reverence and in affectionate regard, and no one ever accompanied him on a ward visit without picking up some important principle of diagnosis or prognosis or receiving some useful hints in regard to treatment. He maintained a voluminous correspondence both with foreign colleagues and with former pupils, and in this his width of interest and his memory were admirable.

Professor Caird had a great gift for delineation. This had been acquired in his early years in connexion with making sketches of plants. He had great facility with the pencil, and added to the value of his notes in surgical cases by making water-colour sketches; he has left a valuable collection of drawings and paintings illustrating cases and operations. His services in this respect were in great demand by his colleagues when some commemorative drawing or menu card for a medical dinner was required, and many ingenious and amusing drawings by him are preserved. Even the walls of his smoking-room in the house which he occupied for many years in Charlotte Square had been decorated by his hand with beautiful and vivid frescoes of scenes from ancient Egyptian life. At medical dinners and social gatherings in Edinburgh he was also a welcome guest; his talent for making amusing observations and his gift of song were in constant request.

The funeral took place at the Dean Cemetery on November 4th, and was attended by a large number of representatives from various medical bodies in the city. The pall-bearers included three sons—Dr. Karl Caird, Dr. Colin Caird, and Mr. Francis Caird. Among those present was Sir Robert Philip, President-Elect of the British Medical Association, Professor Russell, Mr. Alexander Miles, Mr. C. W. Cathcart, and Mr. Henry Wade. Professor Caird is survived by a widow, three sons, and two daughters.

The following appreciation has been received from Mr. C. W. Cathcart, C.B.E., F.R.C.S., consulting surgeon to the Royal Infirmary, Edinburgh:

It is with much diffidence that I respond to the request to add a few personal notes to the obituary record of my life-long friend, Francis M. Caird. He and I first met in the class of practical botany under Professor John Hutton Balfour in the seventies of last century. He was a demonstrator and I a student. In my efforts to cut sections of wood and leaves with a razor for the microscope, he helped me so kindly and successfully that I looked to him and to no other when any difficulties arose. Moreover, in our Saturday excursions for field botany he knew the names—popular and scientific—of all the wild flowers, and could tell us generally some interesting points about them. Before long other students besides myself used to

gather from him all the information we required. At that stage his ability, courtesy, and gift for teaching became well recognized in the botany class. Soon he and I became fast friends, and we remained so to the end, when the sudden cardiac failure last week carried him to the grave. The impression he made on his friends was that of a man of great energy and outstanding ability. In addition to his purely professional studies he read widely in history and general literature, and when such subjects were raised in conversation could emphasize his points by illustrations from his well stored memory. His ready wit and sense of humour added a spice both to his teaching and general conversation. Caird as a dresser and clerk in Professor Lister's wards was one of the many enthusiastic followers of his chief. It was an important part of his training while a student to come under the spell of a man who was as great in his devotion to the poorest patient as he was penetrating in scientific research. Looking back on Caird's career, one can see that he was always on the look-out for new ideas. He assisted the late Dr. Berry Hart in making the first frozen sections to illustrate human anatomy that were undertaken in Edinburgh. As operating assistant to Dr. Angus Macdonald, who practised gynaecological surgery after Keith went to London, Caird developed much skill in this department of abdominal surgery. From this he went on to the surgery of the intestinal canal, and became one of the pioneers in Scotland in this line of work.

Others, no doubt, will refer to Caird's success as a teacher when he attained full rank in the Infirmary and University. Those who knew him in his younger days recognized that this was only the fulfilment of his early promise.

Mr. HENRY WADE, C.M.G., D.S.O., M.D., F.R.C.S., surgeon to the Royal Infirmary, Edinburgh, writes:

Mr. Caird was undoubtedly a magnificent teacher, and for these qualities all his students owed him a profound debt of gratitude. At the same time, he won from all, in addition to an admiration for his genius, a deep and abiding love for him as a man—an unsought tribute earned by him unconsciously. Who could resist his fascination? He seemed to tell you daily what a fortunate man you were to have chosen so splendid a profession; what a joy it was to render such services to humanity; how happy you must be to be so trusted, and how hard you must work to merit truly such a trust. He seemed to tell you that some day even you would get your commission as an ensign and be allowed to carry the colours, and that he knew he could trust you to guard the honour of the regiment of surgery in the fight that never ceased. In the operating theatre he was never spectacular. He seldom spoke to his assistants or students. All his conduct told you that you were there as a privileged spectator. The interest of the patient then alone was considered, however grave the operation, or however trivial the service to be rendered. Mr. Caird's standard of surgical honour was equalled by his surgical courage. Especially as the pioneer of abdominal surgery in the Edinburgh Medical School he frequently accomplished what was looked on as a surgical miracle, and these patients never forget their saviour. Although the calls of surgery were ever so insistent and ever met, Mr. Caird never failed to find time for other interests. The secret of how this was achieved was revealed to those privileged to assist him in his private practice. The tedium of the long train journey to a consultation was lessened by a volume of his favourite Carlyle's *Frederick the Great*, or the most recent work on Egyptology or botany. To go with him on a holiday during the summer vacation was a joy given to some of us. In everything Mr. Caird was generous to an extreme degree; many suspected, but only those intimately associated with him in his private work knew, the extent of this. The honour of the service rendered was often insisted on as in itself a sufficient reward. To the wounded officer who had insisted on being treated as a private patient and who wished to recompense him, he said, "I have operated on you; you have fought for me, and I am still your debtor." Mr. Caird died as he had lived, quietly and happily. The cup that was at his lips he carefully replaced; his head sank forward, and he passed peacefully to his maker.

# WILLIAM EDWARD FOTHERGILL.

WILLIAM EDWARD FOTHERGILL, M.A., M.D.,  
Professor of Clinical Obstetrics and Gynaecology, Manchester  
University; Senior Surgeon for Women, St. Mary's  
Hospitals, Manchester; Consulting Gynaecological  
Surgeon, Manchester Royal Infirmary.

It was a great shock to his many friends to hear of the sudden death of Professor W. E. Fothergill, at the early age of 61, when he seemed to be enjoying excellent health and undiminished energy. He attended the annual dinner of the Glasgow graduates on November 4th, and was apparently in his usual buoyant spirits. After making a speech he complained of feeling ill, and when attempting to leave the room collapsed and died a few minutes later in the ante-room.

William Edward Fothergill was born in 1865 at Darlington. He came of an old Quaker family in direct descent from the elder brother of the famous

eighteenth century Quaker physician Dr. John Fothergill. At the age of 17 he was sent to the University of Edinburgh, where he had a very distinguished career, graduating in the first place in arts, then in science, and finally in medicine, taking the degree of M.B. in 1893 with first class honours, and the Buchanan Scholarship. In 1897 he proceeded to the M.D. degree, which he obtained with first class honours and the gold medal; later he was awarded the Milner - Fothergill gold medal. After a period of study in Jena and Paris he returned to Edinburgh, and held resident posts in the Edinburgh Royal Infirmary and the Royal Maternity Hospital. He was then appointed assistant to the professor of obstetrics, Sir Alexander Simpson.

He had now decided to devote his life to obstetrics and gynaecology, and as Edinburgh seemed to be overcrowded, he looked around for a new sphere of action, and decided upon Manchester. To most people it would have seemed a hopeless task for a young man without a claim on any of the local hospitals to carve a position for himself, but by sheer dogged determination and his ability to make himself useful and indispensable to senior men he not only did this, but eventually obtained the highest appointments in this branch of medicine in his adopted city.

He was a skilled pathologist and a good artist, and this stood him in good stead in his early days, as he helped many of the senior men to describe and illustrate the cases which they wished to publish; moreover, he established the first clinical laboratory at the Manchester Royal Infirmary. He was soon appointed assistant lecturer to the professor of obstetrics, Sir William Sinclair, and later was put on the staffs of both the Southern Hospital and the Northern Hospital as assistant surgeon for women. In these early days he published his well known *Manual of Midwifery*, which was used extensively in Manchester, Edinburgh, and other centres. Some years later the Southern Hospital was amalgamated with St. Mary's Hospital, and he became assistant surgeon to the combined hospitals; soon afterwards he was appointed assistant gynaecological surgeon to the Manchester Royal Infirmary.

At the university he held successive appointments for thirty years, first as assistant lecturer, then full lecturer,

and finally, in 1920, was elected to the chair of systematic obstetrics and gynaecology, which he exchanged for the chair of clinical obstetrics and gynaecology in 1925. In these hospital posts, which he held for so many years, Fothergill acquired a large clinical experience and was recognized as a sound diagnostician and operator, but probably his greatest asset was his command of the English language and his ability to express himself both in speech and writing. Often has it happened at a board meeting when some subject had been discussed though no one was able to find the exact words to express it, Fothergill would take a piece of paper and without hesitation write down the exact formula all had striven for in vain. This ability of easy expression stood him in good stead, and he poured out a steady stream of writing which contained good, sound material, expressed in language easy to understand and delightful to read.

Reference has already been made to his textbook on midwifery; at a later date he wrote a companion volume, a *Manual of Diseases of Women*, and published in a volume a series of lectures to midwives and maternity nurses; all ran into many editions. This gift was unstintingly placed at the disposal of any of his younger colleagues, and many of these, of whom the writer is one, gratefully acknowledge the help and instruction he so lavishly gave when they were preparing their first papers. This facility of easy expression, combined with a wonderful memory, which supplied an apt illustration for any point under discussion, made him a brilliant and arresting teacher.

In private life Fothergill was a delightful companion; endowed with a great gift of humour and a fund of stories which suited every occasion; it was impossible to be dull in his presence, and before the death of his wife he was always seen at his best when presiding at the happy little dinner parties they delighted to give, or surrounded by a group of friends he had collected in his house after some scientific meeting.

Fothergill always rebelled against conventionality, and this sometimes made him express his opinion somewhat brusquely; but behind this manner lived a kindly soul ready to see the other side when put to him quietly. His hobbies were always spent in unfrequented beauty spots, where he was perfectly happy studying plant and animal life or in sketching, in which both he and his wife were very proficient, and he often spoke with pleasure of his beloved Yorkshire dales. Although he had no family of his own he was greatly interested in young people, and never happier than when he was stimulating the undergraduates' athletic activities. As president of the athletic cricket and Rugby football clubs, and lately of the regular union, he was no mere figurehead, but was a regular attendant at all matches and the subsequent suppers; he enjoyed them as much as any youth present.

In 1895, the year he settled in Manchester, he married Edith, the daughter of the late J. Dulton Wood of Chelsea. This proved an ideal marriage, for both had the same hobbies and pleasures; they were inseparable companions.

Photograph by

PROFESSOR W. E. FOTHERGILL.

[Lafayette, Manchester.]

When his wife died, six years ago, it seemed for a time that he would not recover from the loss; but lately much of his old buoyancy of spirits had returned, and he seemed to have many years of useful life before him when the blow suddenly fell, and in a few moments he had passed beyond the veil. Fothergill had a great personality, which impressed itself upon all who came in contact with him, and he will be greatly missed by a large circle of friends.

W. F. S.

### EMIL KRAEPELIN,

Formerly Director of the Psychiatric Clinic at Munich.

PROFESSOR EMIL KRAEPELIN, whose death was briefly announced last week, was one of the most distinguished psychiatrists of modern times, and his work has been the stimulus for a vast amount of research in the sphere of mental disorder.

Kraepelin was born in 1856 and grew up in Neu-Strelitz in modest circumstances. Under the influence of his elder brother, Carl, well known as a biologist, he acquired early an interest in the natural sciences. At the conclusion of his high-school education he determined to study medicine in order to become a psychiatrist. He commenced his medical studies in Leipzig in 1874, and in 1875 continued them at Würzburg, attending Rinecker's clinic, which was devoted to the study of dermatology and psychiatry. There he gained a prize for an essay on the influence of acute diseases on the origin of mental disorder. After passing his medical examinations he became assistant to Bernard Gudden, succeeding Forel, in the Munich Kreis Asylum and Clinic. Here he wrote his first treatise, which was on the abolition of punitive measures; it attracted considerable attention. Subsequently he went as assistant to Flechsig at the Leipzig Clinic, but left it to work in the Erbschen Polyclinic and in Wundt's laboratory. In 1883 Kraepelin returned to Munich, having shortly before published the first edition of his textbook. In 1884 he became head physician in the Leubus Institution, and later director of the Medical Institution and Sanatorium in Dresden. After this he spent four years at Dorpat, attaining the position of professor of psychiatry at the early age of 30 years. His next move was to the University of Heidelberg, where he spent thirteen busy and fruitful years. He was here in a position to study the course and outcome of his cases, and thus to gain experience which enabled him in 1896 to formulate his conception of dementia praecox as a distinct disease entity.

In 1904 he assumed the directorship of the newly established psychiatric clinic at Munich. This clinic soon began to attract the attention of psychiatrists, who flocked from all parts of the world to attend his post-graduate courses of instruction, and also to gain insight into the administration of a mental clinic for uncertified and early cases. Kraepelin gathered around him workers of the highest distinction, and the team work which is so essential in any endeavour to solve the problems of mental disorder thus became possible. He always realized to the full the importance of the association of clinical and pathological work. At Munich he was able to correlate his clinical teaching of dementia paralytica, dementia praecox, and other psychoses with the important pathological discoveries of Nissl and Alzheimer, and also with the neuro-pathological and serological investigations of Spielmeyer and Plant. Kraepelin's earlier associations with Wundt led him to concern himself with the elaboration of psychological experimental methods and their application to the problems of clinical psychiatry; in this way he obtained fruitful results from investigations into the psychical effects of poisons, alcohol, hypnotics, tea, morphine, etc., and also of the effects of protracted mental and physical activity.

Kraepelin was without question a great clinician, and his name will always be associated with his classification of the biogenetic psychoses. By applying the criteria of course and outcome to a mass of hitherto undifferentiated clinical material, he was able to formulate the two outstanding conceptions of the relatively benign manic-depressive insanity and the relatively malignant dementia

praecox group, and in thus producing order out of chaos he gave an impetus to psychiatry to which has been largely due its unquestioned progress in recent years. This is not the place to attempt a summary of the vast amount of work for which Kraepelin was responsible, and perhaps his great textbook of psychiatry affords the most striking evidence of his industry and genius.

In 1922 Kraepelin retired from the management of the Munich Clinic in order to devote his energies to the development of the German Institute of Psychiatric Research founded by him in 1917. The story of its founding reveals the astonishing fact, to use Kraepelin's own words, that a great enterprise, requiring millions of marks, and serving in the first instance purposes of pure science, had been carried into execution, even amid the tumult of war, in little over a twelvemonth. The preparatory work dated back to the pre-war period, but the scheme had to give place to the great task of the day, until, on January 6th, 1916, with the subscription of the first half-million marks, the possibility of its materializing came within reach. In 1917 was held the first public meeting at which the position of the institute with regard to psychiatry could be made plain, and in 1919 five of the seven departments originally projected had begun their work, each under the leadership of a well known man of science. The functions of this institute were outlined in a masterly summary of the problems of psychiatry and of the methods of investigation which were required for their elucidation.\* The conception of dementia praecox opened up a new vista to the younger psychiatrists in this country, though the older psychiatrists were less ready to discard the clinical ideas of their generation. Kraepelin was held in the highest esteem in Great Britain, however, and in recognition of his great services to psychiatry he was elected in 1909 an honorary member of the Medico-Psychological Association. Several of his works have been translated into English. On the occasion of the commemoration of his seventieth birthday the *Psychiatrisch-Neurologische Wochenschrift* published a number of articles appreciative of Kraepelin's career as one of the outstanding figures in the history of modern psychiatry, and it is a source of satisfaction that in this series one contribution appeared from the pen of the late Sir Frederick Mott, as President of the Royal Medico-Psychological Association, and another from that of Professor G. M. Robertson, who undertook this duty on behalf of the editors of the *Journal of Mental Science*.

By the death of Professor Kraepelin psychiatry has undoubtedly lost a great clinician, teacher, scientist, and administrator.

### JAMES ERNEST LANE, F.R.C.S.,

Consulting Surgeon to St. Mary's Hospital and to the London Lock Hospital.

THE death of Mr. James Ernest Lane deprives St. Mary's Hospital of the last remaining link with its founders: Samuel Armstrong Lane, his great-uncle, and James R. Lane, his father, were respectively surgeon and surgeon to out-patients to the hospital when its doors were opened in 1851.

Ernest Lane was born on July 24th, 1857, at 1, Grosvenor Place, S.W. He was educated at Lancing College and at Magdalen College School, Oxford. He entered St. Mary's as a student in 1875. He was a keen athlete, and his stalwart figure is familiar to St. Mary's men in the photographs of the hospital Rugby football team of his day. He won many events in the hospital sports, and on one occasion was the winner of the United Hospitals hurdles. He qualified as M.R.C.S.Eng. in 1880, and in the same year was resident medical officer to the hospital. In 1881 he was appointed demonstrator of anatomy, and this post he held until, in 1888, he succeeded Edmund Owen as lecturer. In 1882 he had obtained the F.R.C.S.Eng. diploma. For seventeen years he lectured for four days a week at nine o'clock throughout the winter, and never once during that

\* Reference should be made to an article, Ends and Means of Psychiatric Research, in the *Journal of Mental Science*, April, 1922.

OBITUARY.

NOV. 13, 1926]

time was he late. Generations of St. Mary's men will remember Lane's nine o'clock lecture as their first introduction to the study of medicine, and many will call to mind the dry sarcasm which rewarded a particularly wild shot at answering the questions which always followed his lecture. The writer, when a student, was his prosecutor, and well remembers Lane's greeting when he arrived late one Monday morning. "I presume, Mr. X., your late arrival is a mark of contrition for the dissection on which I am to lecture." Lane was editor of the ninth and last edition of Heath's *Practical Anatomy*, which appeared in 1902.

In 1891 he was appointed surgeon to out-patients at St. Mary's. He had already become a member of the staff of the Lock Hospital, and his name rapidly became known as an authority on venereal diseases. It was with this sphere of work that most of his writings dealt, and many of the articles on this subject in "System" or "Index" were from his pen. His distinction in this respect was recognized when the Royal Commission on Venereal Diseases was set up in 1913 and he was made one of its members. His association with the London Lock Hospital lasted in all for forty-seven years, and the following appears on the minutes of the Board of Management, dated December 17th, 1925:

"That this Board having heard the letter addressed to the Chairman from Mr. Ernest Lane, resigning his position as honorary senior surgeon, owing to his prolonged illness, resulting from his serious accident in November, 1925, accept the resignation with deep regret.  
"The association of Mr. Lane's family with the Hospital dates back to 1816; his father and great-uncle having held the position of honorary surgeon before him, while Mr. Lane commenced his connexion in 1878, ultimately rising, as they did, to the highest post on the staff.  
"The Board, in grateful remembrance of these long family records, desire in particular to place on their Minutes an expression of their deep appreciation of the great services Mr. Lane has rendered."

After an unusually long spell in the out-patient department Lane was appointed surgeon to St. Mary's Hospital in 1904, and continued in office until his retirement in 1922. He was unfailingly generous and unselfish in his dealing with his juniors, who had much for which to thank him in the readiness with which he allowed them full opportunities for work in the beds which were under his charge. At all times he commanded respect by his absolutely straight and well balanced attitude in matters affecting the welfare and internal conduct of the hospital and medical school. His popularity was exemplified by his enthusiastic reception when he was chairman of the annual dinner of past and present students in 1910. He remained to the end devoted to the school which three generations of Lanes have served. In 1914, when war was declared, he was on the staff of the 3rd London General Hospital, and worked with that unit throughout as a major in the R.A.M.C., T.F. He examined in anatomy at the Conjoint Board and for the F.R.C.S., and was for many years a member of the Court of Examiners of the Royal College of Surgeons. He was elected to the council of the College in 1913 and served until 1921. He was one of the honorary secretaries of the Section of Surgery of the Newcastle Meeting of the British Medical Association in 1893, and upon-Tyne in 1893. He was a prominent Freemason, and was one of those chiefly instrumental in founding the Sancta Maria Lodge in connexion with his own hospital; for nearly twenty-five years he was its secretary, and to him, in greatest part, the outstanding success of the lodge is due.

Not long after his retirement from active work at St. Mary's he sustained a serious accident, being knocked down by an omnibus in Regent Street. This left him bed-ridden. For three years he endured his discomforts and disabilities with exemplary patience until he passed away peacefully on November 4th at the Star and Garter Home, at Richmond, where he was cared for by one of his former pupils.

In 1900 he married Miss Gertrude P. Woram, but leaves no family. Our deep sympathy is extended to his widow. The funeral took place at the Old Fulham Cemetery on November 8th, and was attended by many of his former colleagues, his old pupils, and other personal friends.

SIR CHARLES RYAN, K.B.E., C.B., O.M.G.,  
Major-General, Australian Army Medical Service.

MAJOR-GENERAL SIR CHARLES SNODGRASS RYAN died on October 24th on the Orient s.s. *Otranto*, which had just reached Adelaide from England. He was born on September 20th, 1853, in Melbourne, the son of Charles Ryan, of Derriwait, Upper Macedon, Australia, and grandson of Henry Ryan, of Kilfera, co. Kilkenny. He was educated at Melbourne Grammar School and at Edinburgh University, where he graduated M.B. and C.M. in 1875; he studied also at Paris, Vienna, and Bonn. He joined the Turkish army as a surgeon in 1876, and served for two years, first in the Turco-Servian and later in the Russo-Turkish war, in 1876-78. He served with the Turks throughout the siege of Plevna, and was the only British officer present in these operations, when Ghazi Osman Pasha put up a magnificent defence of improvised earth-works, formerly unknown, while the regular Turkish forts fell easily before the Russian advance. For his services he received the Turkish Orders of the Medjidie and Osmanli, as well as the Turkish war medal. After returning to Australia he became surgeon, and later consulting surgeon, to the General Hospital and Children's Hospital at Melbourne, a member of the Faculty of Medicine of Melbourne University, medical officer of the Governor-General of Australia, and principal medical officer of the Commonwealth Military Forces in Victoria. When the late war began he came to Europe with the Australian Army, as P.M.O., with the rank first of colonel and later of major-general, and served as such at Anzac in Gallipoli peninsula, in France, and in England. He received the C.B. in 1916, the C.M.G. and K.B.E. in 1919, and the Volunteer Decoration. He was the author of a work, *Under the Red Crescent*, in which his war experiences in Turkey were described. In 1883 he married Alice, daughter of the Hon. Theophilus Sumner, M.L.C., of Victoria. She died in 1923, leaving one son, Lieut.-Colonel R. S. Ryan, D.S.O., and one daughter.

CUTHBERT BALFOUR PAUL, F.R.C.S., M.B.,  
Ch.B. (Edin.).

Surgeon to the Cumberland Infirmary.

WE regret to announce the death of Mr. Cuthbert Balfour Paul, who died on October 25th, in his fiftieth year, in a nursing home in Amsterdam, from erysipelas. In company with a party of English surgeons he had been visiting a number of the principal Dutch hospitals.

Mr. Paul was the third son of Sir James Balfour Paul of Edinburgh, for many years Lyon King of Arms, and was educated at Edinburgh Academy and University, where he graduated M.B., Ch.B. in 1900, and obtained the diploma F.R.C.S. in 1903. After holding the posts of resident house-surgeon at the Chalmers Hospital and the Sick Children's Hospital, he became private assistant to Sir Harold Stiles, and worked under him for six years. In 1904 he was appointed assistant surgeon to the Chalmers Hospital, and in March, 1910, assistant surgeon of the Hospital for Sick Children, having entire charge of the surgical out-patient department. In 1912 he was elected assistant honorary surgeon to the Cumberland Infirmary, and soon established a large practice in Carlisle. During the war he performed valuable service at the Cumberland Infirmary, and was visiting surgeon to the Red Cross Hospital at Murrell Hill House. He took an active interest in the progress of the Cumberland Infirmary, and two years ago was appointed one of the honorary surgeons; since there was no vacancy at the time, the statutes had to be amended to enable the committee to pay him this compliment.

Mr. Paul was associated with Sir Harold Stiles in translating into English the fifth German edition of Professor Kocher's standard *Textbook of Operative Surgery*. He was a member of the British Medical Association.

Dr. JOSEPH CANTLEY, who died suddenly on October 23rd, at his residence in Manchester, received his medical education at Trinity College, Dublin. He obtained the L.R.C.P., L.R.C.S.Ed., the L.R.F.P.S.Glasg., and L.M. in 1890, and the L.M. of the Rotunda Hospital, Dublin. Dr. Cantley had practised at Higher Crumpsall, Manchester, for more than thirty years, and was a well known figure at medical meetings, where his independent outlook was always much appreciated. He had been a member of the Lancashire and Cheshire Branch Council of the British Medical Association since 1915, and was chairman in that year. Since 1919 he had been vice-chairman of the Branch, and also a member of the Representative Body. He leaves a widow and four children.

Dr. CONSTANCE MURIEL MARRAT (*née* Willis), who died of pneumonia at Woking on October 10th, in her thirtieth year, received her medical education at the London (Royal Free Hospital) School of Medicine for Women and St. Mary's Hospital. In 1921 she graduated M.B., B.S.Lond., and obtained the diplomas M.R.C.S., L.R.C.P. She held the posts of obstetric officer and resident anaesthetist successively at St. Mary's Hospital. Her career was then interrupted by a long illness, but in 1924 she became assistant resident medical officer at Nayland Sanatorium for six months, and subsequently at Dagenham Sanatorium for more than a year. In 1925 she married, and shortly after was appointed deputy assistant medical officer of health at Woking, where her sympathy and skill with the mothers and children quickly increased the attendance at the clinics. She was a member of the British Medical Association. A colleague writes: Dr. Marrat had a wide circle of friends, who will miss her ever-ready interest and sympathy on all matters, small and great. She was keen, neat, and methodical; had she lived she would undoubtedly have built up a good general practice in Woking.

## Medical News.

THE next session of the General Medical Council will commence on Tuesday, November 23rd; the President, Sir Donald MacAlister, Bt., K.C.B., M.D., will take the chair at 2 p.m. and give an address. The Council will continue to sit from day to day until the termination of its business.

THE annual dinner of the Medico-Legal Society will be held at the Holborn Restaurant, London, on Friday, December 10th, at 7.15 o'clock, with the President, Lord Justice Atkin, in the chair. At the meeting of the society to be held at 11, Chandos Street, Cavendish Square, W., on Thursday, December 2nd, at 8.30 p.m., a communication will be made by Professor Harvey Littlejohn and Dr. Douglas Kerr on "Monoxide poisoning—its increasing medico-legal importance." Discussion will follow.

THE Glasgow University Club, London, will dine at the Trocadero Restaurant, Piccadilly, on Friday, December 3rd, at 7.30 precisely. The Lord Rector, the Right Hon. Sir Austen Chamberlain, K.G., will preside, and the Lord Chief Justice will be one of the guests. Any Glasgow University men who, though not members of the club, desire to attend are requested to write to the Honorary Secretaries, 62, Harley House, N.W.1.

THE half-yearly dinner of the Aberdeen University Club, London, will be held at Kettner's Restaurant, 29, Church Street, W.1, on Thursday, November 25th. There will be a reception at 7 p.m., and Professor William Bulloch will take the chair at 7.30 p.m. The price of the dinner, exclusive of wine, will be 10s., and Dr. W. A. Milligan (11, Upper Brook Street, W.1) will be glad to hear from any graduate (lady or gentleman) wishing to attend. Guests may be invited.

AT the meeting of the Post-Graduate Hostel to be held at the Imperial Hotel, Russell Square, W.C.1, on Tuesday, November 16th, Professor C. A. Pannett, F.R.C.S., will lecture on the treatment of gastric and duodenal ulcers, and on Friday, November 19th, Dr. Maule Hall will speak on the practitioner and the public health man. The meetings commence at 9 p.m.; dinner is served at 8 p.m. (price 5s.); and coffee and biscuits at 10 p.m. (price 6d.)

MR. Y. Z. COPE will lecture for the Fellowship of Medicine on acute intestinal obstruction at the house of the Medical Society of London, 11, Chandos Street, W., on November 18th, at 5 p.m. On November 19th, at 1 p.m., Mr. Charles Goulden will give a clinical demonstration in ophthalmology at the Royal London Ophthalmic Hospital, and on the same day,

at 2 p.m., Mr. Clifford Morson will give a demonstration in surgery at St. Peter's Hospital. The lecture and the two demonstrations are open to members of the medical profession without fee. From November 15th to December 4th the Royal Waterloo Hospital will hold a course in medicine, surgery, and gynaecology, with special reference to endocrine deficiency, diseases of the blood, thyroid, respiratory diseases, cardiac affections, and rheumatism. St. John's Hospital will hold a four weeks' course in dermatology, commencing on November 15th; there will be clinical instruction and two lectures a week; for those desirous of studying the pathology a series of practical demonstrations will be arranged. At St. Mark's Hospital there will be a comprehensive course in diseases of the rectum from November 22nd for one week. Starting on November 22nd and continuing for four weeks there will be a late afternoon course in neurology at the West End Hospital, 73, Welbeck Street. The London Temperance Hospital will undertake a general practitioners' course (4.30 to 6 p.m.) from November 23rd to December 11th. Courses in obstetrics can be provided at Queen Charlotte's Hospital and the City of London Maternity Hospital; practical courses in anaesthetics can also be arranged; and personal applications may be made to the Fellowship of Medicine for clinical assistantships at the Samaritan Hospital for Women. Copies of all syllabuses and of the general course programme may be obtained from the Secretary of the Fellowship, 1, Wimpole Street, W.1.

DR. A. BROWN KELLY of Glasgow will deliver the Semon Lecture in the Robert Barnes Hall, 1, Wimpole Street, London, on Thursday, December 2nd, at 5 p.m. His subject is "Nervous affections of the oesophagus."

THE Geoffrey E. Duveen lectures in otology will be given this year by Mr. Richard Lake, F.R.C.S., at University College Hospital Medical School. The first lecture (on the mastoid operation) will be delivered on Tuesday, November 23rd, and the second (on otitic intracranial abscesses) on Tuesday, December 7th. The lectures, which are open to all qualified practitioners and to medical students, will be given at 5 p.m. on each day.

THE following members of the medical profession are among the mayors elected in England and Wales on November 9th: Dr. E. Collingwood Andrews (Hampstead), Dr. H. J. Campbell (Dartmouth) re-elected, Dr. Douglas E. Finlay (Gloucester), Dr. W. E. St. L. Finny (Kingston), Sir Thomas E. Flitcroft (Bolton), Dr. J. R. Leeson (Twickenham), Dr. H. Malins (Warwick), Dr. J. H. Nixon (Chippenham), Dr. R. S. Pearson (Lambeth), Mr. Ransom Pickard (Exeter).

DR. DAVID SHANNON, J.P., lecturer in clinical obstetrics in the University of Glasgow, has been appointed a deputy lieutenant of the county of the city of Glasgow.

DR. CHARLES JAMES MARSH, who was honorary surgeon to the Yeovil Hospital from 1880 to 1926, since when he has served it as honorary secretary and treasurer, was honoured on November 3rd by the unveiling in the hospital of a bronze bust of himself. Dr. Marsh was a member of the executive committee of the West Dorset Division of the British Medical Association from 1908 to 1916 and again from 1919 to 1922. He was a member of the Dorset and West Hants Branch Council in 1908 and from 1917 to 1919, and president of the Branch in 1910. He has been a member of the Representative Body since 1923.

A MEMORIAL to Sir Richard Douglas Powell, Bt., M.D., a former President of the Royal College of Physicians of London and physician in ordinary to the King, was dedicated recently by the Bishop of Buckingham at Cheddington Parish Church. The memorial has been given by Lady Powell; it consists of a silver cross and altar candlesticks.

A STAINED glass window, erected in the chapel of the Holloway Sanatorium, Virginia Water, to the memory of the late Dr. W. D. Moore, for twenty-seven years medical superintendent of the institution, was unveiled by Sir Lindsay Smith, chairman of the Board of Management, on October 30th. The dedication service was performed by the Bishop of Guildford.

A BRONZE bas-relief in honour of the late Professor Weill, the eminent paediatrist, has recently been unveiled at the Hôpital de la Charité, Lyons, when speeches were delivered by the ex-Premier, M. Herriot, and Weill's successor, Professor Mouriquand.

ON All Souls' Day (November 2nd) His Highness Maharaja Sir Chandra Shumsher Jung of Nepal had a wreath placed on the grave of Dr. A. C. Inman in Père la Chaise Cemetery, Paris, "in grateful recollection of skilful help and faithful friendship." Dr. Inman was pathologist to Brompton Hospital, and died last July.

THE French Ambassador in London has informed His Majesty's Government that the centenary of Laënnec will be celebrated in Paris on December 13th, 14th, and 15th next, and that Professor Chauffard, of the Academy of Medicine in Paris, is in charge of the arrangements.

SIR HUMPHRY ROLLESTON, Bt., Regius Professor of Physic, University of Cambridge, has been elected as the representative of the University on the General Medical Council for five years, in place of Dr. W. L. H. Duckworth, resigned. Sir Humphry Rolleston has been the representative of the Royal College of Physicians of London upon the Council since November, 1922.

At the recent Clinical Congress in Montreal of the American College of Surgeons honorary fellowships were conferred on Professor Robert Alossandria of Rome, Professor Archibald Young of Glasgow, Sir Ewen Maclean of Cardiff, Professor L. E. Barnett of Dunedin, New Zealand, and Professors John Fraser and David Wilkie of Edinburgh.

THE Board of Trade gives notice that representations have been made to it under Section 10 (5) of the Finance Act, 1926, regarding the following articles: Amldopyrin, barbitone, cocaine, cocaine hydrochloride, guaiacol carbonate, hydroquinone, methyl sulphonal, oxalic acid, phenacetin, phenazone, piperazine, salol, sulphonal. Section 10 (5) of the Finance Act, 1926, is as follows: "The Treasury may by order exempt from the duty imposed by Section 1 of the Safeguarding of Industries Act, 1921, as amended by this Act, for such period as may be specified in the order, any article in respect of which the Board of Trade are satisfied on a representation made by a consumer of that article that the article is not made in any part of His Majesty's Dominions in quantities which are substantial having regard to the consumption of that article for the time being in the United Kingdom, and that there is no reasonable probability that the article will within a reasonable period be made in His Majesty's Dominions in such substantial quantities." Any person desiring to communicate with the Board of Trade with respect to the above-mentioned applications should do so by letter addressed to the Principal Assistant Secretary, Industries and Manufactures Department, Board of Trade, Great George Street, S.W.1, within two months from the date of this notice (October 27th).

THE British Social Hygiene Council (Carteret House, S.W.1) has published in one volume the proceedings of the Imperial Social Hygiene Congress, which was held at the British Empire Exhibition at Wembley in October, 1925. Opening addresses were given by the Right Hon. L. S. Amery, M.P., and by representatives of some of the Dominions. Discussion followed on venereal disease in the navy, army, India, the mercantile marine, the self-governing Dominions, and the Colonies and Protectorates. A paper by Dr. Kathleen Vaughan contained some lurid evidence on the organization of prostitution in Kashmir; and a good deal of discussion took place on the need of protection for sailors in seaport towns. The report of the proceedings furnishes a large amount of information for those interested in venereal disease.

THE International Labour Office has issued six further pamphlets, Nos. 46-51, dealing with acid burns, air of work rooms, dangers arising out of working in alabaster and alcoholic intoxication, anguillulosis, diseases due to the preparation of ethyl alcohol, and injuries by fluorine and hydrofluoric acid. When the series of pamphlets is complete, they will be published by the International Labour Office in a bound volume.

THE St. Andrew's Ambulance Association in Scotland has found its headquarters too small. An appeal made early this year for £30,000 to cover the cost of new premises has already brought in about half that amount. The main feature of the association's work is its motor ambulance service for the transport of cases of accident and illness. During the last year 27,410 calls were made upon the ambulance waggons, and of these cases 13,677 were conveyed in the Glasgow area alone. The patients conveyed to hospitals and other places since the formation of the association number 391,969.

THE first number of the students' journal of the Welsh National Medical School, entitled *The Lecch*, contains articles on the importance of anatomy by Professor David Hepburn, on thyrotoxicosis by Mr. Lambert Rogers, on biochemistry and modern medicine by Mr. J. Pryde, lecturer in chemical physiology, and articles of clinical and general interest. An appeal is inserted on behalf of the Cardiff Royal Infirmary, the financial position of which has been seriously affected by the coal dispute.

THE November issue of *The Prescriber* is devoted to rheumatic diseases, with special reference to the economic aspect. The subjects treated include fibrositis, osteoarthritis, rheumatic heart disease, the relation of goitre to rheumatism, the treatment of chronic rheumatic diseases, and spa treatment. The journal may be obtained from the editorial publishing offices, 6, South Charlotte Street, Edinburgh, price 3s. 6d., post free.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the British Medical Journal, unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the British Medical Journal must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the JOURNAL, should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the British Medical Association and the British Medical Journal are MUSEUM 9361, 9362, 9363, and 9364 (internal exchange, four lines).

THE TELEGRAPHIC ADDRESSES are:

EDITOR of the British Medical Journal, Aitology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Mediscera Westcent, London.

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

### QUERIES AND ANSWERS.

"MEDICAL MAYOR" asks for advice in the treatment of a girl, aged 3 years, infested with *Taenia solium*.

BEDS FOR PAYING PATIENTS IN SMALL HOSPITALS.

DR. C. R. DYKES (Buckhurst Hill, Essex) asks for information with regard to country hospitals, with from thirty to fifty beds, providing accommodation for some private patients.

WARTS AND EGGS.

WE have received the following replies to Dr. Leonard Williams's question in the JOURNAL of October 22nd (p. 763). Dr. J. M. MACPHER (Middlesbrough) writes: It was a common belief in West Argyllshire that warts could be caused by washing the hands in the water already used for the boiling of eggs, and in many parts of the East of Scotland and in Yorkshire they refuse such water to wash dishes or use in any way.

DR. A. MACMANUS (Rusholme, Manchester) writes: The belief in the association of warts with freshly boiled eggs is fairly common. Some persons will not touch the shell of a warm egg, but use a napkin when transferring it to an egg cup.

THE PLACENTA AFTER PITUITARY EXTRACT.

"R. E." wishes to raise the question with which the following note concludes: After a prolonged second stage in a primipara, aged 27 years, 1 c.cm. of pituitary extract was given and delivery by forceps was then immediately effected. The third stage lasted three and a half hours, presumably owing to the uterus going into tonic contraction. The puerperium was normal. Should the placenta have been manually removed after an hour, according to most orthodox teaching?

CHILBLAINS.

DR. ERNEST A. MILNER (Kington, Herefordshire) writes: If "C.P.J." will give calcium chloride 10 grains thrice a day instead of the lactate—which is an unreliable salt—and parathyroid 1/4 grain once or twice daily, I think he will find the chilblains can be kept at bay.

DR. H. V. CANTOR writes: It may be advisable to try a method advocated by Leonard Mitchell in the *Medical Journal of Australia*, October 2nd, p. 449, which should be consulted for details; the treatment may be summarized thus: The hands may be treated by firmly fitting rubber gloves worn at night; the toes by a cuff of a rubber glove worn around the foot or by a thin piece of sponge rubber held in place by a piece of sticking plaster. The pressure must be firm.

DR. NORMAN HODGSON (Newcastle-on-Tyne) states that he has had good results in the treatment of chilblains from the following mixture, to be taken for three days during frosty weather: Calc. carb. 66 grains, acid. lact. conc. (sp. gr. 1.21) 144 min., aq. menth. pip. ad 12 oz.; 1 oz. thrice daily.

DR. MARY G. CARDWELL (Oldham) writes to suggest the following regime: The patient, sitting in a warm room, has two bowls, one of hot water, the other of cold, into which the hands or feet, as the case may be, are plunged alternately, care being taken to finish up with hot water. The part is then rubbed with a warm rough towel and afterwards with olive oil. This should be done twice daily and should be begun in early autumn. "Success depends on the conscientious carrying out of the treatment combined with vigorous friction. Cod-liver oil and malt is a useful adjunct."

## INCOME TAX.

## Partnership Assessment.

"DURHAM" has received a notice of assessment which he finds inexplicable in certain respects—for instance, £402 is deducted for personal allowance due to the two partners.

It is unfortunately the fact that the law does not provide for partners to be separately assessed, with the result that the joint assessment, which is really the sum of the liabilities of the partners, is not understandable by others. This is particularly the case in medical partnerships where the partners bear their locomotion expenses individually, so that the assessment, even before the allowances are deducted, is not properly divisible into the partnership shares. We advise "Durham" to write to the inspector of taxes asking him to state separately the partners' shares of the £842 gross assessment. As regards the £402 allowance, it may be that one partner has had £43 allowed from some private assessment—for example, on untaxed property or interest.

## Expenses.

"W. G. M." has been in partnership three years, and his locomotion expenses (owing to the substitution of a motor car for a motor cycle) have been very much greater in the last year than in the first two. The inspector of taxes refuses to allow more than the average of the three years.

This is correct. As the law stands the firm is assessable upon the average profits of the three years—that is, upon the average of the amounts by which the gross earnings for each of those years exceed the expenses of those years respectively. It would, of course, be incorrect to deduct average expenses from the gross earnings of a single year. This applies to the running expenses referred to in "W. G. M.'s" letter; the "depreciation" allowance, say 15 or 20 per cent., is a deduction from the average and should be claimed accordingly. A point which may be worth attention is that "W. G. M." may include in his claim for expenses the original cost to him of his motor cycle less the amount realized for it on sale—the claim to apply to the year in which the sale takes place—by way of obsolescence allowance.

## LETTERS, NOTES, ETC.

## ROYAL COLLEGE OF SURGEONS OF ENGLAND.

DR. ALEXANDER THOS. SCOTT (Holloway, N.7) writes: I think that the attention of your many readers who are Fellows or Members of the Royal College of Surgeons of England should be drawn to a striking example of the dilatory methods of the Council. The new (supplemental) charter of 1926 gives women Fellows and members, and also licentiates in dental surgery, equal rights with men, not that this privilege amounts to much in the case of the last two classes. This charter was signed by His Majesty in July last—that is, four months ago; yet the Council has apparently not altered or amended By-law No. 26, which forbids women to attend meetings and vote at the College. The said rule is that women at the annual meeting of Fellows and members on November 18th will not be allowed admission except into the gallery, and when there will not be permitted to speak or vote. Apparently the women will be denied their rights until November, 1927, at the earliest. It will be interesting to men Fellows and members to see in what manner the women will express their opinion of such treatment.

## RECOVERY AFTER APPARENT DEATH.

We have previously referred to the progress made by our contemporary, the *Kenya Medical Journal*, the clinical and scientific contributions to which are often of general interest. The September issue contains a brief report which almost inevitably recalls the old tag, *Ex Africa semper aliquid novi*, inasmuch as it relates to the temporary recovery of consciousness several hours after apparent death. Dr. H. M. Shelley relates how he found the apparently dead body of a native woman, whose throat had been cut; the floor of the hut was covered with blood, the woman was not breathing, and there was no evidence of any cardiac action. The body was transferred to the mortuary in the neighbouring town of Zomba, and three hours later preparations were made for a necropsy. It was then found that the woman was breathing slowly and deeply, and a rapid, thready pulse was palpable in the radial artery. The cut vessels were quickly ligatured, a tracheotomy tube inserted, the skin sutured, and intravenous saline administered. Within thirty minutes from the beginning of the operation the woman regained consciousness, and was removed into hospital, where she gave an account of the assault to the police. Four hours later she died from asphyxia, due to blood in the trachea. The injuries included a linear incision in the neck 4½ in. long, left internal and external jugular veins, the left superior thyroid artery, and the trachea completely. The woman had been apparently dead for nearly six hours before receiving treatment, and yet in the space of a few moments regained full consciousness. Dr. Shelley's explanation is that strangulation had preceded the injury, causing asphyxia, with the result that the blood remained fluid much longer than usual. In preparing the body for the necropsy, pressure was exerted upon the woman's chest, allowing the lungs to take in a fresh supply of air and at the same time

causing a flow of blood, which possibly reached the brain and stimulated the respiratory centre to action. The day was very hot, so that the woman could not have experienced any great loss of body heat.

## THE DETERMINATION OF SEX.

DR. N. MCCONNELL BOYCE (Romford, Essex) writes: Some four or five years ago I read in the *JOURNAL* a letter from a general practitioner. He wrote on the determination of sex and suggested that, when conception took place prior to a menstrual period, a male child resulted and a female when conception was after a period. That letter aroused my interest in this matter, and I have lost no opportunity to verify the rule it laid down. I am convinced that the riddle of sex is no riddle at all, and that the simple rule propounded in that letter is the law of sex determination. During the past few years it has been interesting, when booking a maternity case, to try and find out exactly when conception took place with relation to the period. In the majority no help could be given by the patient, but those few who were able to state matters definitely produced at birth that sex which was expected. It has been my practice to broadcast the rule to all whom I thought it would help. Results have been hard to obtain, but I know at least three people who have been grateful.

## TREATMENT OF PRURITUS ANI.

DR. T. W. PRESTON (London, S.E.) writes: I was much interested in the letter by "J. S." published in your issue of October 23rd (p. 763) on the subject of pruritus ani, and particularly in his remarks about failure to wash the hands after defecation. It is a small matter, which many may perhaps consider unworthy of much attention, but I agree with "J. S." that its importance might with advantage be emphasized more by those concerned with the public health. I would suggest further that facilities for washing the hands without extra charge should be provided in all public lavatories maintained by municipal bodies for persons who have made use of a water-closet. At the present time one cannot wash one's hands after defecating in a public water-closet without paying the full charge for "wash and brush up." It is unreasonable to expect everybody to do this, and thus dirty habits are indirectly encouraged by the public health authorities.

## MICROSCOPE LAMPS.

A CATALOGUE of illuminating apparatus for microscopes has been forwarded to us by Ogilvy and Company (20, Mortimer Street, W.1), who bear a well known name in the British optical industry. Certain improvements have been made with a view to arriving at an ideal electric lamp for microscopical research. The lamp described embodies a hood (in the shape of a vertical brass cylinder), and so constructed that it gives the minimum reflection, thus lessening the experience by those who undertake observation for long periods. The iris diaphragm serves the double purpose of regulating the size of the light source as required and enabling the user to project an accurately focused image. The condenser system is fitted with centring screws, so that the condenser may be accurately placed in relation to the permanently fixed iris diaphragm, and the electric bulb is of the half-watt type, but made with a special mixture of glass, so as to present an exceedingly fine opal surface. This diffuses the rays from the filament, and when there is sharp focus no structure or granulation appears in the field of view. The catalogue contains particulars also of a new form of substage lamp in which the illumination is directly on the microscope, and of a mercury vapour lamp for research workers who require light in the ultra-violet region.

## WATER ANALYSIS.

AT the last meeting of the Society of Public Analysts Mr. J. W. Haigh Johnson, M.Sc., presented a critical review of the methods of analysing waters, sewage, and effluents, and made suggestions for their improvement. He found that present methods yielded results which were often unreliable and inconsistent. Recent modifications in sewage treatment have greatly increased the amount of nitrogen oxidation products in sewage treatment and have thus increased the difficulties. A comparison of the results given by the Wanklyn, Kjeldahl, acid chemical, and biological processes has indicated that, in its present form, the first is too vague, whilst the acid chemical test yields only a fifth of the result obtained biologically. Mr. Johnson described a method of combining the Wanklyn test and the alkaline oxidation method, and made suggestions for improving the Kjeldahl test and the biological determination of absorbed oxygen.

## A WARNING REPEATED.

IN our issue of January 3rd, 1925 (p. 56), Dr. Hubert Cox (Edgbaston) wrote to say that a man had been making use of his name and address in the Laton district for the purpose of obtaining money from doctors. He suggested that any practitioner receiving a visit from such a person should communicate with the police. He now learns that this man is "working the London area."

## VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 40, 41, 42, 43, 46, and 47 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 44 and 45.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 215.

F. H. JACOB, M.D., F.R.C.P., President.

## THE NATURE OF MALIGNANT NEOPLASIA AND TREATMENT OF THE DISEASE WITH LEAD.

A SYMPOSIUM BY MEMBERS OF THE STAFF OF THE LIVERPOOL MEDICAL RESEARCH ORGANIZATION.

VICE-CHANCELLOR ADAMI, before reading the introductory remarks of Professor Blair Bell, said:

It is with profound disappointment on your part, and indeed on the part of all concerned, that I appear before you this morning in place of Professor Blair Bell. This packed audience has gathered here to hear him describe the methods and progress of his work upon the treatment of cancer. He himself appreciated acutely the action of the Nottingham executive in inviting him and granting a whole morning in this Section for the full presentation of the work accomplished by himself and his colleagues in Liverpool during the past five years. But, a little more than fourteen days ago, he experienced an acute septic attack with a temperature so high that for a time his life was in danger. When I saw him two days ago, while he was on the road to recovery, he was still in bed, and any idea of his coming to Nottingham was clearly out of the question. In these circumstances he asked me to deliver his introductory paper. Naturally I would greatly like to seize this opportunity to give you my own views regarding this work, and the arrest of cancer. You will understand, however, that in loyalty to Professor Blair Bell, this morning I cannot and must not break into the programme arranged by him. One thing, however, I may perhaps be permitted to say, and this with a full knowledge of the doubts and aspersions that have been thrown upon Professor Blair Bell and our work in Liverpool, and it is this: From the first moment when, more than five years ago, Professor Blair Bell told me in confidence what he was doing, I have been so impressed with his scientific method of approach to the subject that I have given him my whole-hearted support, nor have I ever once discovered any departure from the strictly scientific attitude during all these years. And, this being so, I have constantly helped forward the work, and particularly the co-operative method of attacking the many problems involved, being convinced that, where such a spirit of scientific approach towards every aspect of the problem was manifested by all concerned, despite temporary ill report the work must eventually redound to the credit of the University of which I find myself head, and of which so many members of the professorial body are co-operating in this investigation. I am sure that those who listen to the succession of papers to be given this morning can only come to one conclusion.

## THE LIVERPOOL CANCER RESEARCH ORGANIZATION.

BY

W. BLAIR BELL, B.S., M.D., Hon. F.A.C.S.,

Professor of Gynaecology and Obstetrics in the University; Gynaecological and Obstetrical Surgeon, Liverpool Royal Infirmary; and Director, Liverpool Cancer Research Organization.

THE Liverpool Cancer Research Organization, which we hope in the future to call "The Liverpool Medical Research Organization," has been in existence for over three years.

I have never had any doubt as to the best way of attacking not only the problem with which we are now dealing, but also other complex pathological states, like the toxæmias of pregnancy, on which our present work promises to throw some light.

Our Organization was made possible in the first instance, and for over two years, by the generosity of a few Liver-

pool citizens who found the money required, and formed a committee, the support and sympathy of which have been assets of incalculable value. I have recorded elsewhere the names of those who have so loyally helped us.

During the last eight months our Organization has been in a measure self-supporting: all fees received from patients for consultations, operations, biochemical examinations, injections, and nursing-home accommodation are received by the committee, and this body defrays the expenses in connexion with both the clinical work and laboratory investigations. As far as it is possible to guarantee such a thing, it is the intention of the committee to conduct the work on the present lines for five years longer. It is, however, highly improbable that during the whole of that time enough will be earned in fees, year by year, to support the Organization in its present form, let alone endow it. It is sincerely to be hoped, therefore, that sufficient financial support will be forthcoming to relieve the committee from anxiety in this matter.

Let me now describe the constitution of our Organization and the way in which we are attacking our present problem.

First, it was deemed impossible with the money at our disposal to employ an entirely whole-time staff of the variety and distinction necessary for the work in hand. Secondly, careful consideration made it clear that for each principal investigator entire freedom of action and method was essential if we were to secure the interest, co-operation, and harmony we sought to promote.

The following plan, therefore, suggested itself. The heads of the various departments in the University of Liverpool, whose expert knowledge could be brought to bear on different aspects of the same line of attack, were consulted, and invited to take part in the work of the Organization in their own laboratories, with the aid of whole-time qualified research workers, laboratory assistants, and other facilities. There was a most generous and ready response, and, in spite of certain freely expressed forebodings, our belief that, in a serious effort of this kind, the personal equation of all would be reduced to parity has been completely justified; consequently goodwill, cordial co-operation, and some success in our common task have been the result. In this way, too, it came about that what I have called an "aggregate mind" was brought into being, to make up for the inevitable deficiencies that must be found in an isolated mind, however elastic, in respect of such a multifaceted subject as that of malignant disease.

Co-ordination was sought not only in regard to the purely scientific research investigations—that is, in physical and biological chemistry, pathology, pharmacology, and animal experimentation, but also in connexion with the clinical aspects of the subject.

The following is the present staff of the Organization.

Director: W. Blair Bell (P).

Assistant Director: L. Cunningham (P).

### Chemistry—

Physical Chemistry: W. C. McC. Lewis (P), M. Jowett (W), H. Millet (W), J. Brooks (W).

Biochemistry: R. Coope (H), L. Cunningham (P).

Pharmacology and Toxicology: W. J. Dilling (P).

Pathology: E. E. Glynn (P), R. W. Brookfield (W).

Animal Experiments: W. Blair Bell (P), M. Datnow (P).

### Clinical Work—

General Surgery: H. F. Woolfeuzen (H), W. R. Williams (P), J. B. Oldham (P).

Medicine: John Hay (H), L. Cunningham (P).

Anæsthetist: H. L. Patch (P).

### Special Surgery:—

Gynaecology: W. Blair Bell (P), S. B. Herd (P), M. Datnow (P).

Throat and Ear: H. V. Forster (P).

Eye: T. H. Bickerton (P).

Radiography: R. E. Roberts (P).

Public Health Officer and Statistician: C. O. Stallybrass (P).

Secretary: Edward Carey (P).

(W)=Whole-time. (P)=Part-time. (H)=Honorary.

In addition there are four assistant secretaries and six laboratory assistants, all whole-time. Financial obligations have been fairly and generously adjusted by the committee.

Such an arrangement resembles, of course, the general method adopted by the Rockefeller Institute and some of more famous American clinics, such as those of the Mayos and Crile. But I think we go even further in the solidarity, absence of friction and timing of our machinery, and also in the concentration of every unit of energy on the matter in hand.

In order to illustrate our methods of research and practice I must now discuss briefly the question with which we are immediately concerned and the difficulties encountered.

In the first place, long years of thought and study of every aspect of the problem, particularly perhaps the clinical side, forced me to the conclusion that it is of considerably lesser importance to seek to enumerate the many, as I believe, so-called "causes" (really predisposing factors) of cancer, than to discover the nature of the cancerous process itself—that is, the character of the change from normal growth to cancerous development. I do not, of course, wish to imply that such etiological information is of no importance, for it may be of the greatest value in the prevention of the disease, as I have stated elsewhere.<sup>1</sup> Nevertheless, we shall always be faced with existing malignant disease, and be called upon to treat it.

Now, my own views, often expressed, as to the nature of malignant neoplasia may be very briefly stated as follows:

There are many extrinsic and intrinsic factors which can produce the "precancerous condition" in, or in relation to, the cells concerned—radiations of various kinds, heat, trauma, infection, toxæmias, senescence, and the rest, all of which reduce the vitality of the cell—a condition which may terminate in recovery, death, or in reversionary development in order that the cell may live. It seems probable that the metabolic disturbance leading to the change may be one of oxygen starvation. The importance of this will be made apparent later.

The ancestral type to which the cell seeks to return in the reversionary process is that of the chorionic epithelium, which has the power of invasion and erosion of blood vessels in its search for nutriment. Malignant neoplasia except, *ipso facto*, in the case of chorion-epithelioma, is, therefore, a specific process of dedifferentiation from high specialization back towards or to the most distant ancestral type—the chorionic epithelium.

If this be so, we should expect on scientific investigation to find that the chorionic epithelium resembles the malignant cell in structure, function, chemical composition, and, therefore, also in toxicological affinities.

It must be clear from what I have said that the working hypothesis presented a formidable array of scientific problems for elucidation before a generalization could be formed. The energy with which each has been attacked, and the amount of convincing confirmatory evidence obtained, say much for the spirit that has prevailed.

In physical and biological chemistry Professor Lewis, and his whole-time associates, Dr. Corran, Dr. Jowett, Dr. Millet, and Dr. Brooks, have undertaken most arduous and difficult work, and have done a great deal to establish the similarity of chemical composition and function of the chorionic epithelium and malignant tissues, as you will hear directly.

Not only this: Professor Lewis and his fellow workers have done much research in connexion with the preparation of the material made by them for our use in the treatment of patients, and they have studied also the fate of lead in the blood stream.

In pathology, Professor Glynn has placed at our disposal his great experience, and has written full and illuminating reports on the tissues submitted to him. There is one matter I must mention concerning this work, and it is that it has been a revelation to us how many lesions are diagnosed as malignant by surgeons without the authority of a pathological report based on histological study. We ourselves rarely undertake the treatment of a case on clinical evidence alone; and our insistence on obtaining tissues for section has led to the discovery that cases are not always malignant as supposed. Any criticism that might be offered in respect of cases treated by us without a piece of tissue having been removed for section would be scientifically justifiable.

In addition Professor Glynn, working in conjunction with Dr. Brookfield, has endeavoured to ascertain the nature of the earliest effects of lead on malignant cells, for gross

necrosis gives no clue as to the character of the proceeding changes. Moreover, Dr. Brookfield has made interesting observations on the character of basophil stippling of the erythrocytes.

Professor Carter Wood, Director of the Crocker Institute for Cancer Research in the Columbia University, who has so cordially undertaken the investigation of the changes produced by lead on large transplantable rat tumours, has consented to-day to be regarded as a corresponding member of the Liverpool Cancer Research Staff, and he will lay before us the striking results he has obtained.<sup>3</sup> I wish publicly to thank him for his broad-minded, scientific, and generous support at a difficult time.

Dr. Hendry, Dr. Annett, and myself have described the action of lead on the chorionic epithelium of the rabbit.<sup>2</sup>

The toxicological action of lead on the normal growth of plants and animals, commenced by Mr. Patterson and myself, has been fully studied by Professor Dilling, who has, moreover, given us much valuable clinical assistance by his investigations into the action of lead on the gastrointestinal and vascular systems. Professor Dilling has, too, determined the toxicity of a variety of preparations of lead suggested for, or used in, the treatment of cancer.

Lastly, Dr. Cunningham will discuss at some length our work on the treatment with lead of malignant disease in the human subject. I may say here that we chose lead for our first attack because of its action on the chorionic epithelium—an action I observed first many years ago. Nevertheless, the mere fact that the chorionic epithelium and the cancer cell are similar in nature, and that lead is specifically toxic to both, is not enough; we have yet, as you will gather, either to improve and render consistent our results, and to protect our patients from the harmful effects of lead poisoning, or we must find some other substance that will act after the manner of lead on malignant tissues but be less toxic generally.

In spite of all this, I hope that when you have heard my colleagues discuss the various aspects of our work, and my summary of it, you will agree that our generalization concerning the nature of cancer is soundly supported in every direction, for the elucidation of the nature of cancerous development is the first step towards the successful treatment of malignant disease.

## SOME PHYSICO-CHEMICAL AND BIOCHEMICAL ASPECTS OF MALIGNANT NEOPLASMS.\*

BY

W. C. M. LEWIS, M.A., D.Sc., F.R.S.,

Professor of Physical Chemistry, University of Liverpool.

It is necessary to point out in the first place that what I have to say deals only with a particular phase of the general problem presented by malignant neoplasms. It may be well to emphasize that the object of my remarks is twofold—namely, to indicate the nature of those physico-chemical and biochemical results already attained which bear upon the problem, results as yet not very numerous, and still more to indicate the very much larger field in which future investigations are likely to lead to conclusions of value in connexion with the processes which underlie malignancy.

### Electrical Conductivity and Permeability of Malignant Tissue.

In the first place I would draw your attention to an almost purely physical property—namely, that of electrical conductivity. It has been shown that cancerous tissues, freshly removed from the body, have a higher electrical conductivity than normal tissues under the same conditions. Crile has succeeded in comparing the electrical conductivity of the outer growing part of cancers with the central non-

\* Abstract of a more detailed paper.

growing parts, and has found that the outer growing part has the higher conductivity. He quotes the following:

|                                  | Specific Conductivity. |
|----------------------------------|------------------------|
| <i>Carcinoma of the thyroid:</i> |                        |
| Centre of growth ... ..          | 0.00101                |
| Periphery ... ..                 | 0.00528                |
| <i>Carcinoma of the uterus:</i>  |                        |
| Centre of growth ... ..          | 0.00493                |
| Periphery ... ..                 | 0.00653                |

Now electrical conductivity depends on the presence and movement of electrically charged atoms or ions—which may be simple or complex in structure—and the increased conductivity necessarily means that the material now possesses an increased permeability to such water-soluble constituents on the part of any membranes or septa in the cells. Fricko and Morse (unpublished), who confined their measurements to cancer of the breast, find that the electrical conductivity is not necessarily raised in malignancy. They find a fairly large number in which it is lowered. These authors lay much greater stress on the value of electrical capacity as an indication of malignancy, the capacity in all the cases examined (55) being decidedly raised as compared with the normal. On the whole, in so far as evidence is available, the electrical measurements tend to indicate increased permeability as a definite feature of malignant tissue.

Let us now consider briefly the question of the alteration in the relative amounts of those substances part of the function of which is that of maintaining a certain degree of permeability or impermeability. It has been shown by Clowes and Frisbie,<sup>1</sup> and confirmed by others, that in actively growing malignant tissue the calcium content is markedly low, whilst that of potassium is high.

It has been known for a long time<sup>2</sup> that calcium tends to alter an emulsion consisting of water as the continuous phase with droplets of a fatty oil suspended therein into an emulsion of the reverse type in which water is suspended in droplets in a continuous medium of oil. The former type of emulsion has a high electrical conductivity and permeability for water-soluble substances, the latter type has scarcely any conductivity and will not permit water-soluble substances to pass through it. Clowes has applied these ideas to the permeability and impermeability of a cell. Naturally it is nothing more than a rather crude mechanical picture, and it might be improved perhaps if we regard the role of calcium, in so far as this function is concerned, to be that of preventing even temporary or incipient perforation of the cell membrane. If there is a deficiency in calcium—as seems to be beyond dispute in the case of malignant tissue—the increased permeability and electrical conductivity observed are to be expected.

#### Phosphatide and Cholesterol Content of Malignant Tissue.

But calcium is not the only substance involved in permeability. We have to take account of the phosphatides, lecithin with its congeners cephalin and sphingomyelin, together with cholesterol, which is not a phosphatide. These substances are usually found associated together along with other fatty material (glycerides).

In agreement with the work of Seifriz<sup>3</sup> and of Bhatnagar,<sup>4</sup> Dr. Corran, working in my laboratory, found that lecithin is an emulsifying agent which favours the formation and maintenance of an emulsion in which the oil is dispersed in water, the water being the continuous phase.<sup>5</sup> Such a system possesses high permeability for water-soluble substances. On the other hand, cholesterol is an emulsifying agent which favours the reverse type of emulsion—namely, one in which the water is dispersed in the form of fine droplets in a continuous medium of oil. This system has a very low electrical conductivity and is not permeable to water-soluble substances. Emulsification experiments were also carried out in which both lecithin and cholesterol were simultaneously present and a definite antagonistic action was observed. The type of emulsion was found to depend upon the relative amounts of lecithin and cholesterol present. An excess of lecithin gives rise to an emulsion in which water is the continuous phase.

It is obvious that the ratio of these two substances is a

highly significant one in determining which type of emulsion will be formed. The transfer of these considerations to the question of cell permeability appears legitimate, and we would expect to find that those cells in which the lecithin to cholesterol ratio is high should be those possessing marked permeability.

In this connexion mention may be made of a rather limited set of analyses carried out by Bullock and Cramer<sup>6</sup> on the lecithin-cholesterol content of malignant tissue in rats, from which it may perhaps be inferred—though the evidence in this instance is not conclusive—that the lecithin-cholesterol ratio is higher in rapidly growing tumours than it is in slowly growing tumours. A somewhat extensive series of determinations of the lecithin-cholesterol contents of human tissues and tumours has been carried out in my laboratory by Dr. Corran and Dr. Jowett, the results of which seem to leave little doubt but that in malignant growth the ratio of lecithin to cholesterol is excessive. This is shown by the following table, which gives the average values obtained. Further determinations are in progress.

| Human Tissues.              | Per cent. Water. | Per cent. Phosphatides (on dry wt.). | Per cent. Cholesterol (on dry wt.). | Phosphatide-Cholesterol Ratio. |
|-----------------------------|------------------|--------------------------------------|-------------------------------------|--------------------------------|

The somewhat larger content of water and the high ratio of lecithin to cholesterol are, in the light of emulsification experiments with fatty oil, precisely what one would expect to go hand-in-hand with the increased permeability of such tissues. Incidentally also the analytical results obtained for the chorion are strong evidence in favour of the view advocated by Blair Bell regarding the fundamental similarity between malignant growth and the chorion itself—that is, in favour of dedifferentiation as characteristic of cancer.

#### The pH (Reaction) of Blood and Tumour in Malignancy.

In view of the marked permeability to water-soluble substances indicated above, it would be natural to inquire whether there is any departure from the normal behaviour on the part of cancerous subjects in respect of the pH (that is, the acidity or alkalinity) of the blood and the tissues affected. As regards the whole blood of human subjects there is no detectable deviation from the normal value. The effects, if any, are completely masked by the buffering action of the blood and by the ability of the liver and muscles to take up lactic acid. Any effects, if present, would probably only be detectable near the site of the growth in the blood issuing from that region. This condition has been realized by C. F. and G. T. Cori<sup>7</sup> in the case of Rous sarcoma in chickens' wings and also in one instance of a human subject with a large sarcoma in the forearm. In the experiments with the chickens the tumour, which was of about the size of an egg, was produced in one wing only, the other wing being normal. These authors found that the blood which had passed through the tumour contained distinctly more lactic acid than the blood which had passed through the normal wing. Whether this points to an acid condition in the growing part of the tumour itself is uncertain.

In experimental tar cancer (in rabbits), according to Remond, Sendrail, and Lasalle,<sup>8</sup> in the precancerous stage the pH of the plasma is considerably lowered (from an average value of 7.31 to an average of 7.17). Incidentally the authors find the ionic calcium of the blood diminished, and conclude, in agreement with others, that calcium has an inhibiting effect on tumour growth.

An altered reaction in either direction may be expected on general chemical grounds to alter—raise or lower—the activity of enzymes and the stability of certain chemical complexes. Experiments are in progress in my laboratory upon the pH of cancerous tissue, using the glass electrode technique worked out by Mrs. Kerridge in A. V. Hill's laboratory.<sup>9</sup>

*Antitryptic Activity of the Blood in Cancer.*

Antitryptic action is usually ascribed to the interaction (adsorption) of trypsin enzyme with some constituent of the serum. The blood of cancer patients usually exhibits an increased antitryptic activity.

That the antitryptic activity of the serum is due to lipoids appears first to have been suggested by Schwartz (1909), and later by Sugimoto (1913). Jobling and Petersen confirm this view, and as a result of their carefully carried out experiments generalize to the extent of attributing antitryptic action to esters of unsaturated fatty acids, the more unsaturated the acid radicles the greater the antitryptic action. It is necessary to point out, however, that the role attributed by Jobling and Petersen to phosphatide has been questioned by several workers.<sup>10</sup> Thus Teale and Bach conclude that serum antitrypsin is protein in nature. It is quite possible that we have to do with a lecithin-protein complex. Neuberg<sup>11</sup> suggests that the antitryptic action is of the nature of a protective effect against excessive enzyme activity.

Unfortunately in most of the work considered here there is no record of the reaction or pH of the system having been determined, and, in view of the known amphoteric natures of enzymes on the one hand and of material such as lipoids and proteins on the other, it is to be expected that an alteration in pH may exert a profound influence on the effects produced.

*Digestibility and Autolysis of Tissues, Normal and Malignant.*

If the physico-chemical phenomenon of permeability is to be regarded as of biochemical significance we should expect that it would play a significant part in such a process as that of digestion of tissue by enzymes. It would be expected, in fact, that increased digestibility would go hand-in-hand with increased permeability, this condition being presumably a favourable one for the transport of enzymes and products of enzyme action in either direction. A comparison of normal living and dead tissue supports this. The permeability in the latter condition is regarded as being greater than that in the former, the increased permeability of dead tissue being ascribed to changes brought about by toxic substances such as acids.

At the same time the digestibility of living and dead tissue respectively is known to be very different. Thus Northrop, in a recent paper<sup>12</sup> on "The resistance of living organisms to digestion by pepsin or trypsin," finds that while pepsin or trypsin is quickly removed from solution by dead organisms these enzymes are not able to penetrate into normal living organisms. Since the presence of excess lecithin in the membranes and septa of malignant tissue has been regarded as one of the causes of the increased permeability of such tissues (to water-soluble materials), one would anticipate at first sight that dead malignant tissue would exhibit an even greater permeability and consequently greater digestibility than normal dead tissue. Present results are conflicting and the question is under investigation.

The lack of agreement serves to raise the question whether the permeability attributable to lecithin in living (malign) tissue is not something different from the permeability associated with dead material. Gurchot<sup>13</sup> speaks of the latter as irreversible permeability, due to the excessive action of acid. On the other hand, the permeability of living tissue due to the large phosphatide-cholesterol ratio is conceivably reversible. In fact, the lipid seems to have a dual function in this connexion. By its presence it endows the membrane with permeability to water-soluble constituents, but at the same time it reacts with proteolytic enzymes to inhibit their action. This mode of interaction has already been referred to in connexion

with the antitryptic action of blood in malignancy, and it is even more clearly brought out by the work of Biederman<sup>14</sup> on both plant and animal cells, to the effect that "during life both types of tissue are indigestible, but when dead the preliminary extraction of the lipid materials markedly increases digestibility." Biederman concludes that the failure of living animal tissue to undergo digestion is associated with its lipid content.

*Glucolysis in Malignant Tumours.*

We now turn to another aspect of malignant growth—namely, glucolysis. An examination of the literature available up to the present serves to show that of the chemical processes usually regarded as of importance for cell life—namely, oxidation, reduction, hydrolysis, proteolysis, glucolysis—the only one associated with cancerous tissue which exhibits outstanding divergence from the normal is that of glucolysis; that is, the conversion of carbohydrate into lactic acid—one molecule of glucose forming two molecules of lactic acid. This has been rendered very certain by the work of several independent investigators, and in particular by that of Otto Warburg and his co-workers.

In normal tissues (muscle) Meyerhof has shown that there is a "reversible equilibrium" between carbohydrate and lactic acid. The formation of lactic acid proceeds freely, but the reverse reaction requires a supply of energy and proceeds only when respiration is taking place, the latter providing the necessary energy for the re-synthesis of the sugar. One molecule of oxygen respired brings about the disappearance of from one to two molecules of lactic acid. Evidently the net amount of glucolysis observed under given conditions depends on the amount of respiration taking place. If the respiration is high compared with the glucolytic power—as is the case for normal tissue—there will be little net glucolysis; that is to say, under aerobic conditions in the normal tissue there is little observable glucolysis.

In cancerous tissues, on the other hand, the most important and characteristic feature is that appreciable glucolysis occurs under aerobic conditions, the glucolysis being in fact not much less than that under anaerobic conditions. Warburg's results have been confirmed by experiments carried out in my laboratory. Quantitatively, for Flexner-Jobling rat carcinoma the tissue converts twelve molecules of sugar into lactic acid for every one which it oxidizes, the metabolism being therefore predominantly glucolytic. The markedly glucolytic character holds good, according to Warburg, for all malignant tissues, whether human or non-human, carcinomata or sarcomata. The following table, due to Warburg, indicates the kind of result obtained. It will be observed that the ratio of aerobic glucolysis to respiration is very large for malignant growth. (The numerical values quoted denote the number of cubic millimetres of gas evolved (or absorbed) at normal temperature and pressure per milligram of dry tissue per hour.)

| Tissue.                                      | Respiration. | Anaerobic Glucolysis. | Aerobic Glucolysis. | Quotient. |
|--|--------------|-----------------------|---------------------|-----------|
|  | I.           | II.                   | III.                | III/I.    |
| (a) Malignant.                               |              |                       |                     |           |
| Flexner-Jobling rat carcinoma...             | 7.2          | 31                    | 25                  | 3.9       |
| Human carcinomata (mean of 13 various types) | 5.1          | 21                    | 14                  | 3.1       |
| (b) Innocent Tumours (human).                |              |                       |                     |           |
| Nasal polyps ... ..                          | 5.2          | 14                    | 4.6                 | 0.9       |
| Bladder papillomata ... ..                   | 13.3         | 26                    | 16                  | 1.2       |
| (c) Normal Epithelium (resting).             |              |                       |                     |           |
| Liver (rat) ... ..                           | 11.6         | 3.3                   | 0.6                 | 0.05      |
| Pancreas (rabbit) ... ..                     | 4.6          | 3.4                   | 0                   | 0         |

The fact that it is glucolysis which is the predominant one in malignant tissue is significant in that glucolysis is a process which yields much more energy than do processes such as proteolysis or lipolysis. The heat liberated per molecule of glucose split to lactic acid is 24,000 calories.

The energy derived from glucolysis in Flexner-Jobling rat carcinoma is some 40 per cent. of the energy derived from oxidations,<sup>15</sup> and hence a considerable part of the energy developed by carcinoma cells is due to glucolysis. That this is useful energy is shown by the fact that supplying glucose to the cells when these were kept under anaerobic conditions increases their survival period.<sup>16</sup>

It is of interest to compare the behaviour of malignant tissue as regards glucolysis with that of embryonic tissues (chick)—which are already differentiated. It has been found that glucolysis under anaerobic conditions is large, and that under aerobic conditions it is small owing to the considerable respiration. This has led Warburg to the generalization that high glucolytic power is a general characteristic of growing tissue, but appreciable glucolytic activity under aerobic conditions is characteristic only of unordered growth. Warburg regards the chorion as analogous to embryonic tissue. On the other hand, Murphy and Hawkins<sup>17</sup> find that chorionic villi possess the high ratio of aerobic glucolysis to respiration characteristic of cancerous tissue, and use the phrase that "the type of metabolism was similar to that of frank malignant tissue"; a conclusion which supports the view advocated by Blair Bell regarding the fundamental similarity between malignant growth and the chorion.

Although it is a matter of the first importance to have shown, as Warburg and others have shown, that excessive glucolysis is a characteristic accompaniment of malignant growth, the still more fundamental problem remains unsolved as to the nature and origin of the conditions which have made excessive glucolysis possible, and as to the organ or organs involved in the production of such conditions.

To return to the mechanism of glucolysis itself, it is very generally believed that the transformation of glucose to lactic acid involves among other stages the formation of an intermediate compound between glucose and phosphoric acid—namely, lactacidogen—which is formed and decomposed as a result of enzyme action. Any chemical reagent introduced into the tissue which reacts and thereby modifies the rate of formation of this intermediate or its rate of decomposition to lactic acid would evidently exert a marked effect upon the rate of growth of malignant tissue. Whether part of the function of lead is to effect this is a problem upon which we are engaged at the present time. In this connexion it may be mentioned that, according to Warburg, Posener, and Negelein,<sup>18</sup> the presence of bicarbonate or phosphate ions is essential for glucolysis.

As regards a possible part played by lecithin in glucolysis it may be recalled that E. L. Scott<sup>19</sup> has shown by the boiling-point method that in alcohol solutions lecithin combines with glucose, and he concludes that union likewise occurs in aqueous media.<sup>20</sup> Such union will almost certainly alter the chemical reactivity of the glucose, and the high lecithin-cholesterol ratio in malignancy may therefore be a favourable circumstance in retarding growth by inhibiting excessive glucolysis. It is proposed to investigate this point experimentally.

#### Infiltration.

Probably the most outstanding characteristic of malignant growth is its capacity for infiltration into neighbouring tissues, a property which is likewise possessed by the chorion, this similarity constituting further evidence in favour of the view advocated by Blair Bell, to which reference has already been made. Any information upon the mechanism of infiltration is therefore of importance as a contribution to the study of malignancy.

At the present time little is known regarding this aspect of the problem. Reference may be made to the work of Bierich<sup>21</sup> and Bierich and Rosenbohm<sup>22</sup> in connexion with the spreading of cancer, induced in the epithelial tissue by the action of tar, into the underlying connective tissue, wherein certain characteristic changes are brought about in the collagen, such changes being the preliminary step in the act of infiltration. According to these authors, the characteristic changes in collagen consist of imbibition of the collagen fibres and the simultaneous appearance in greatly increased numbers of "elastic" fibres, produced mainly by the hydrolytic decomposition of the collagen

fibres, the elastic fibres possessing a marked affinity for resorcin fuchsin. On treating specimens of the normal dorsal skin of mice with various acids and bases, and mixtures of these with salts, changes are produced in the structure and nature of the collagen; but, according to the authors referred to, the reagent which brings about changes most closely analogous to those observed in the spread of cancer is lactic acid.

These authors conclude that the cancer cells in the epithelium by degradation of carbohydrate produce lactic acid, which diffuses into the connective tissue below, where it brings about the changes referred to, thereby favouring the infiltration. It is believed that the degradation products of the connective tissues themselves influence the course of the processes occurring in the epithelium. The role thus ascribed to lactic acid is significant in view of the marked glucolysis characteristic of malignant cells. This is pointed out by Bierich. It must be emphasized that these considerations apply only to the preliminary step in infiltration.

#### Lipolytic (Esterase) Activity in Malignancy.

There is a further point to which I wish to draw attention—namely, to lipolysis. Falk, Noyes, and Sugiura<sup>23</sup> have shown that the aqueous extracts of Flexner-Jobling rat carcinoma exhibit only a very slight lipolytic effect as tested by the hydrolysis of a series of esters. Results of the same order of magnitude were obtained for certain normal tissues—namely, aqueous extracts of heart, skeletal muscle, and brain. On the other hand, marked lipolytic activity was obtained in the extracts from normal liver and kidney, and to a less extent from normal testicle, spleen, and lung. Analogous results were obtained by Rona and Lasnitzki,<sup>24</sup> using tributyrin as substrate.

It is very reasonable to suppose that the decreased lipolytic activity in malignant growth accounts in part at least for the characteristically high ratio of phosphatide to cholesterol found therein. The marked permeability of such tissues would then be logically related to the decreased lipolytic (esterase) activity, since permeability is mainly associated with the high lecithin content.

Turning from the tumour to the serum, it may be recalled that Bauer<sup>25</sup> found that every human serum examined contains fat-splitting enzymes which are greatly decreased in carcinoma and advanced phthisis. It has been recently pointed out<sup>26</sup> that "lipolytic activity is increased by calcium chloride, to which potassium chloride is antagonistic." In malignancy the calcium is decreased, and consequently it would be expected, in the light of the above statement, that lipolytic activity would be diminished in the case of malignancy—a conclusion in agreement with observation.

We have here followed the usual convention in using the term "lipolytic" as referring to any fat or ester hydrolysing enzyme. The necessity for a more exact terminology is indicated by Bloor:<sup>27</sup>

"It appears desirable to differentiate between enzymes which hydrolyse the fats readily—the true lipase—and those which work slowly on the fats but readily on the esters of the lower fatty acids and on lecithin, and which may be called esterases. Lipases appear to be present in significant amounts only in the intestinal secretions of the pancreas and other intestinal glands, while the esterases are of quite general distribution. In view of the importance of lecithin as an intermediate stage in fat metabolism the esterases are therefore to be regarded as potentially of considerable significance."

Returning to the malignant growth itself, we might be disposed at first sight to attribute the decreased lipolytic activity to an altered reaction of the growth. Since, however, the pH of the serum of cancerous subjects is normal, and at the same time there is a diminished lipolytic activity of the serum, it is evident that we cannot regard decrease in lipolytic activity as due simply to alteration in pH, although such may exert a secondary influence. It seems more reasonable to conclude that the diminution in lipolytic activity, both in tumours and in serum, is due to a real decrease in production of esterases.

Although reference has been made to esterases at some length, it is not suggested that these enzymes occupy any very unique position in the problem of cancerous growth beyond the excessive lipid-cholesterol ratio of tumours. To the chemist perhaps the most striking thing about metabolic change in general is the rapidity of the chemical

changes involved in spite of the absence of marked acidity or alkalinity. Purely chemical experience shows that hydrogen ion and hydroxyl ion are the two most active reagents, especially in aqueous media, and the fact that neither of these rises to any considerable magnitude (say decinormal) in biological material is a demonstration that numerous chemical changes involved in such systems must depend on the intervention of enzymes. Glucolysis itself is known to involve enzyme action. It is evident, with our present very rudimentary knowledge of the number, nature, mode of action, and source of biological enzymes, that attempts at correlation would be altogether premature. While this is so, it should not blind us to the fact that progress in such a problem as the present consists to a large extent in attempts at logical correlation—that is, in disentangling chemical causes from chemical effects. If we are to make any progress in this direction at all it must be by examining in the first place, and in some detail, those processes which exhibit the more striking departure from the normal.

## ADDENDUM.

## On Some Points in Connection with Lead Suspensions.

The finely divided suspension of lead—actually a mixture of metal, hydroxide, and a little carbonate—as used at the present time in Liverpool is prepared electrically by Bredig's method. An aqueous solution containing 0.5 per cent. gelatin and 0.027 per cent. calcium chloride is poured over a layer of assay granulated lead and is sparked for about fifteen minutes, using metallic lead electrodes, the potential difference between the electrodes being about 60 volts. The resulting black suspension is decanted and centrifuged for two to three minutes at 1,700 revolutions per minute until the particles are not greater than  $0.3 \mu$ . After sterilization, sodium, calcium, and potassium chlorides are added to make the suspension slightly hypertonic. The final suspension contains 0.5 per cent. of lead.

The suspension turns white slowly on exposure to air (due to absorption of oxygen) and slowly settles. It can be used safely for injection over a period of about three days. An addition of gelatin (up to 2 per cent.) by increasing the viscosity adds to the permanence of the suspension, but excessive protein is not desirable from the clinical point of view.

The observation has been made by Dr. Brooks that the lead preparation is more permanent in presence of sodium phosphate, which presumably stabilizes it by adsorption of phosphate ions, thereby increasing the negative electrical charges which the particles possess. The concentration of phosphate employed was the same as that in blood. Similar stabilization is produced in serum, and no interaction involving precipitate formation has been observed *in vitro*. On injection, therefore, it may be anticipated that the finely divided particles will be carried to all parts of the circulatory system. Evidence was obtained several years ago by Blair Bell that the tumour exhibits a selective preference for the lead, which is held there in greater proportions than in neighbouring normal tissue. It appears likely that the lead thus localized is slowly converted into ordinary lead ion  $Pb^{++}$ , which is believed to be the really effective agent. It may be mentioned that the protected suspension described is almost entirely free from lead ion, which could not, of course, be injected into the blood stream as such at the concentration employed without producing fatal results. Prolonged dialysis of the lead preparation, however, against water over a period of twenty-four hours indicates the slow production of ionic lead. It should be noted that dialysis itself is a somewhat drastic treatment. Thus, taking the twenty-four-hour period referred to, the concentration of lead ion found by Dr. Millet in the outer water in dialysis amounted to 0.0006 per cent.  $Pb^{++}$ . On the other hand, on simply allowing the lead preparation to stand for twenty-four hours and then ultra-filtering, the amount of lead ion was 0.00004 per cent.  $Pb^{++}$ . The latter is the more significant result of the two for the actual amount of decomposition spontaneously occurring in the lead preparation.

From a chemical point of view the most characteristic reaction into which ionic lead enters is the formation of lead phosphate,  $Pb_3(PO_4)_2$ , the most insoluble salt of the

metal under body conditions. It has been definitely shown by Brooks that in serum the lead suspension is converted to the extent of 85 per cent. into this salt, the remainder of it into carbonate. In view of the presence of alkali phosphate in tissues, it is almost inevitable that this insoluble lead salt is likewise formed; it then may perform the function of rendering the tumour less permeable and tend towards the production of encapsulation, an effect which is sometimes observed.

Further, the great affinity of ionic lead for the phosphate ion suggests an affinity for the radicle  $PO_4$ , and consequently for any substance, such as lecithin, which contains this radicle.<sup>28</sup> Some determinations of the complex formed between lead ion and commercial lecithin showed that the complex contains approximately 12 per cent. of lead. It is not certain, however, whether this represents a true compound or an adsorption. It is self-evident, however, that the essential function of the lead cannot adequately be accounted for or described simply by postulating, or even by demonstrating, its capacity for union (either true compound or adsorption complex) with any given substance or substances. It is necessary to be able to show that such union or unions play a definite role in a process of significance for cell life. If union—say with phosphatide—were all, we would expect from a colloid-chemical point of view that most of the multivalent heavy metals would be similar in action—a conclusion which is apparently contrary to fact. The clinical value of lead is probably to be sought rather in the direction of causing the cessation of certain chemical processes due to enzymes, upon which the activity of the cell depends.

## SOME PHARMACOLOGICAL EFFECTS OF LEAD.

BY

WALTER J. DILLING, M.B., Ch.B.,

Associate Professor of Pharmacology, Liverpool University.

THE reasons which led Blair Bell to formulate the hypothesis that lead had some specific retarding influence on the growth of the malignant cell have been frequently recorded by him,<sup>1</sup> and I may say that I regarded his views that the lead ion had a specific toxicity towards embryonic and rapidly growing tissues as unproven from the pharmacological standpoint.

An explanation of its toxic action on living cells might be sought for in the oligodynamic action of the heavy metallic ions—a term applied by Nüggeli to their powers, in extremely dilute solutions, of inhibiting the growth of lower organisms.<sup>2</sup> This oligodynamic action is not confined to any one metallic ion, but is possessed in different degrees by each, while towards certain organisms some show relatively high toxicities, which have earned for them the title of specifics—as, for example, mercury towards spirochaetes, and copper towards algae, etc. There was, therefore, a possibility that lead might be relatively more toxic to the malignant cell or to the agent which excites its rapid growth.

## EFFECTS OF LEAD ON GROWTH.

Blair Bell realized that many influences could act adversely on normal growths, but it seemed important at first to ascertain by simple tests if there was any proof that lead salts had unusual powers in this respect when compared with other metals. Blair Bell and Patterson had previously demonstrated that weak solutions of lead acetate inhibited growth and development of hyacinth bulbs,<sup>3</sup> and Griffith had also shown that lead retarded plant growth, especially of the Leguminosae,<sup>4</sup> but Miss Brenchley's work afforded evidence that other metals in weak solutions had a similar influence on seedlings.<sup>5</sup>

A comparison of the effects in equimolecular solutions of lead nitrate with the nitrates of copper, zinc, beryllium, thallium, and thorium upon the germination and growth of seeds, frogs' spawn, and plaice embryos was instituted to test the question, the last ion being selected on account of its genetic relationship with radium and lead.

In the seed experiments mustard and cress were utilized because they possessed only a small reserve of food. The general conception obtained from them was that lead seemed to be more potent as an agent retarding germination than the other metals tested with the exception of thallium, which killed the seeds, so that they did not germinate on transfer to a normal medium; it was also more potent as an agent retarding growth of the young plant, except copper solutions, in which the seedlings hardly grew at all. The strengths necessary to inhibit germination of seeds were, however, very considerable—for example, 0.1 per cent. lead ion.<sup>6</sup>

A series of experiments with frogs' spawn supplied evidence that where the spawn was laid in leaded water germination was generally inhibited in concentrations stronger than N/20,000, but, since partial germination did occur at and above this strength, the metal is apparently more toxic to the ovum than to the spermatozoon, although duration of exposure may have been a factor. Experiments with large batches of eggs showed that in N/100,000 lead salts only from 20 to 25 per cent. of the eggs germinate, as against 75 to 80 per cent. of the controls; that the free-swimming tadpoles emerge about four days late, and are in size 40 per cent. behind the controls at the end of one month. Comparative experiments with a colloidal lead preparation indicated that with almost equal percentages of lead ion the retarding effects on growth were similar. It should be mentioned that only with strengths above N/5,000 lead nitrate was any film of precipitation visible on the albuminous envelope of the spawn.

In experiments on free-swimming tadpoles supplied twice weekly with fresh food and solution in tap water, it was found that very young tadpoles with external gills were more susceptible to the lead than those with internal gills, and that N/100,000 solutions—or the equivalent of colloidal lead—reduced growth to about one-half the normal at the end of one month.

The other metallic solutions, tested in equimolecular proportions, showed certain differences in effects which may be summarized very briefly. Zinc, copper, and thallium had less effect than lead in checking development of the ovum but were more fatal to the emerged tadpole. Beryllium was relatively inert. Thorium, however, approached its relative lead to some extent in its power of checking germination, but it was much less active in retarding the growth of tadpoles.<sup>7</sup> These results resemble those obtained by Locke many years ago when he found, in comparing copper, zinc, tin, and lead, that copper was the most toxic to tadpoles, zinc less marked, tin devoid of effect, while lead had a very slight toxic action, if any.<sup>8</sup> The results indicate that, of the metals tested, lead has the most powerful action in arresting germination of the ovum, and, in strengths insufficient to kill, was most effective in delaying growth of the free-swimming tadpole.

From experiments on plaice embryos extending over a year evidence was obtained of the retarding influence upon growth of small traces (Pb 1 in 250,000) of colloidal lead in sea-water. The fish tanks, into which fresh sea-water flowed at a known rate, were "leaded" continuously from June to November—the period of growth. In November the leaded fish were 20 per cent. shorter than the controls, and this "setback" persisted through the winter months when, however, normal growth is slow. The test was designed to inform us whether lead had a permanent effect in retarding growth, but casualties occurred in the second year which completely upset the averages; hence it is impossible to say more than that the retarded growth and vitality persisted for at least seven months. Some control experiments on the weights of goldfish in the laboratory, while they afforded information on faunal depletion in lead-polluted streams, did not assist the main problem, as it was found impossible to maintain the weights of the controls.<sup>9</sup>

I may now refer briefly to the relevant literature on the effect of lead on growth. Paul, in 1860, noted among lead workers a high rate of abortion and infant mortality; subsequent writers have fully confirmed his general opinion,<sup>10</sup> although Legge and Goadby regard the case for poisoning of the male germ cell as unproved,<sup>11</sup> but Weller<sup>12</sup> found with guinea-pigs that the offspring of "leaded" males by healthy females was 20 per cent. below normal weight, while "leaded" females had, by a healthy male, a high proportion of stillbirths and offspring about 15 per cent. below normal weight. Weller also found that retardation of growth persisted after birth—a feature noted by Oliver and Chyzer<sup>13</sup> in the children of Hungarian potters—but that when lead administration ceased the production of normal offspring returned. Facts of similar import may be obtained from veterinary reports on animal life in the lead-mining area of Wales; thus, Morgan noted that sheep removed from leaded pastures resumed the production of healthy lambs.<sup>14</sup>

The simple experiments which were instituted to provide evidence for or against a special action of lead on normal growing tissues have served to confirm many observations of others, and the following conclusions seem inevitable: (a) That lead is distinctly more toxic to germ cells and to embryonic tissues than it is to mature tissues; to such an action must be ascribed its sterilizing effect in males, and Weller's observation of aspermatogenesis with atrophy of the germinal epithelium resulting from lead in a guinea-pig<sup>15</sup> has been confirmed by Blair Bell in rabbits.<sup>16</sup> (b) That its adverse influence, in which, I think, the time factor plays a part, is more marked on the ovum and is responsible for temporary sterility and early abortion in females. From Blair Bell's work on pregnant rabbits it appears that the toxic action of the lead is exerted on the chorion epithelium, and that copper, thallium, and thorium, which were tested in view of my results with frogs' spawn, have not this characteristic effect.<sup>17</sup> This is probably the explanation why lead is the most active abortifacient among the metals. (c) That in non-lethal amounts its retarding influence on growth and vitality appears to be inversely proportional to the age of the animal and tends to persist; we may thus explain the undersized and weakly offspring of leaded parents. (d) That the power of inhibiting germination and retarding growth is more a characteristic of lead than of the other metals subjected to examination. It may be added that, from feeding pigeons with pure metals, Hanzlik and Prescho concluded that, as regards power of reducing body weight, the action of other metals was less than that of lead, which they regard as having a specific toxicity.<sup>18</sup> I consider it inaccurate to say that lead has a "specific" action on growth, if we use that term in the restricted medical sense of "peculiar" rather than the wider sense of "definite," because my results show that other metals can produce somewhat similar effects. The evidence is, strictly speaking, in favour of lead having relatively greater powers of inhibiting the germination of cells or of retarding growths of embryonic tissues in strengths which are not toxic to more mature tissues.

At this juncture it was evident that fuller investigation of the effects of lead on normal growing tissues would not further the main issue, and that investigation of the action of lead salts on malignant tumours in animals must be undertaken by a pathologist.

#### TOXICOLOGY OF LEAD.

Subsequent pharmacological work has been largely determined by demands for information about some of the untoward effects in human beings, or concerned with tests for toxicity in the various lead preparations.

#### Action on Intestine.

One complication of the intravenous administration was the occurrence of vomiting and colic. The literature on lead colic is very extensive, but many of the suggested explanations have been based on inadequate evidence. Aub and Miss D. E. Smith<sup>19</sup> must have commenced their investigation about the same time as I did, and their reported findings agree very closely with mine. Examination of the experimental work of Harnack,<sup>20</sup> Hirschfelder,<sup>21</sup> Wassermann,<sup>22</sup> and Siccardi<sup>23</sup> led to the view that the action must be a

local one on the bowel and that the colic was a spasmodic contraction of the muscle; such might be due either to stimulation of the vagus receptors such as is caused by parasympathetic stimulants like pilocarpine, or less probably to paralysis of the inhibitory sympathetic innervation, but more probably to a direct action on the muscle. Experiments were carried out with longitudinal strips of muscle from the intestines of various animals—guinea-pig, rabbit, hare, cat, rat, sheep, and man—kept contracting in a bath of 150 c.cm. of Tyrode's fluid at 37° C., through which a continuous stream of oxygen bubbles passed. The sodium bicarbonate in the Tyrode's fluid was a disturbing factor in that it precipitated a soluble lead salt as carbonate and the pH of the fluid decreased correspondingly. Theoretically the amount of bicarbonate in 150 c.cm. of Tyrode's fluid (0.075 gram) should completely precipitate 0.15 gram of lead nitrate—practically the amount contained in 1 c.cm. of N/1 lead nitrate—and, as the solubility of lead carbonate in water is 0.00017 per cent., negligible results, until all the carbonate ion had been precipitated, might have been expected, but chemical analysis showed that the amount of lead which exists in solution in the bath of Tyrode's fluid increases in proportion to the amount added, and it appears that as the hydrogen ion concentration increases the solubility of the lead increases. There arose then the problem of the fall in pH produced by the added lead salt; to control this factor a series of experiments was done in which Tyrode's fluid containing no bicarbonate was used; the results from these were found to be similar to those obtained with normal Tyrode's fluid.

The effect of adding lead to the bath is to cause first a diminution of the automatic intestinal movements and usually some lowering of the tone. The inhibitory action is first noticeable on the addition of 1 c.cm. of N/100, with which no precipitation occurs—roughly 1 in 150,000 lead ion. Following the inhibitory phase there frequently ensues, with weak lead concentrations, a period of increased amplitude in the contractions, and now the intestinal muscle does not usually respond so effectively to further additions of the same dose of lead.

The second type of effect may be a development of the first, and becomes apparent when amounts of 6 to 7 c.cm. of N/10 lead nitrate have been added—that is, 1 in 2,500 lead ion added and found in solution by colorimetric analysis from 1 in 16,000 to 1 in 12,000. The tracings now show that the inhibitory phase is followed by a wave of augmented tone with reduced or inhibited pendulum movements—a type of colicky contraction. The tone wave is at a maximum from ten to fifteen minutes after the addition of the lead, and then slowly declines, when the pendulum movements may again resume a more or less normal rhythm. Variations in the type occur, including one in which, during the tone rise, very rapid fibrillary contractions are just visible in the tracing. With still larger amounts of lead salt—namely, 1 c.cm. N/1 lead nitrate (Pb 1 in 1,500 added; 1 in 7,500 found in solution chemically)—complete inhibition of movement occurs, and this phase may last for from two to ten minutes; it is succeeded by a rise in tone, often commencing with staircase-like contractions which gradually diminish as the extreme tone is reached. Subsequently the tone declines, and the muscle may again resume good rhythmic movement although still immersed in lead solution.

These effects take place after atropine, hence the tone rise cannot be of vagal origin; after nicotine, hence they cannot originate in ganglia; addition of lead can counteract a pilocarpine tonus, and also a pituitrin and barium tonus, hence the primary inhibitory action might have been due to sympathetic stimulation; and, indeed, it closely resembles the action of adrenaline, but it has been found possible by repeated additions of adrenaline to render the intestine quite insensitive to this hormone—that is, the rhythmic movements can escape from sympathetic control; but even then lead can still inhibit the rhythmic movements and later induce its characteristic tonus. As final proof that the action is on the muscle the same effects have been obtained on a small scale with the nerve-free rings of circular muscle described by Gunn and Underhill.<sup>21</sup>

Such actions have been obtained from lead nitrate, acetate, and chloride, and from basic lead acetate in similar

molecular concentrations; controls have been made of variations of the pH at different periods of the experiment, but its variation does not apparently afford a key to the double action because (a) the fall in pH on the addition of lead tends to return within ten to fifteen minutes to nearly normal; (b) the effect of changing the fluid in the intestine from normal Tyrode with a pH of 7.2 to Tyrode without bicarbonate with a pH of 5.5 merely weakens the contractions; and (c) lead salts produce identical actions in Tyrode's fluid without bicarbonate, while serum solutions of lead and colloidal metallic lead produce similar effects, except that the inhibitory phase is less complete.

With regard to the inhibitory phase, this so closely resembles the action of adrenaline in type and evanescent character that one is inclined to view this action of lead as being on some rhythmic mechanism in or on the muscle peripheral to, but closely associated with, the receptor influenced by adrenaline, because lead acts when adrenaline fails, and yet the inhibition of rhythm by lead is generally so brief that it is obviously not a toxic effect on the muscle substance; again, the fact that adrenaline can act after recovery from lead shows that the latter has not injured the sympathetic receptors. The rapidity of onset indicates that the effect must be mainly a surface one.

The tonic phase is something entirely different; its onset is usually delayed and is gradual. Its commencement may be heralded by the recrudescence of automatic movements, but, as the tone increases, these decline or become fibrillary in type. During the stage of tone, which one believes to be comparable with an attack of lead colic, the effects of other drugs depend on the degree of tonus developed; in mild degrees, pilocarpine-atropine, nicotine, adrenaline, and nitrite reactions can be obtained, but a fully developed tonus remains uninfluenced by large doses of atropine, morphine, nicotine, adrenaline, nitrites, or chloral. Of the drugs named, adrenaline is most commonly effective, but its relaxing action is quite transitory. The addition of sodium phosphate to precipitate the dissolved lead in the bath is sometimes, but not always, effective in reducing the tonus; a change to lead-free Tyrode fluid relaxes the tonus. These results explain why atropine and nitrites have been recommended in the treatment of lead colic by some writers and their efficacy denied by others, and why Blair Bell found that the symptom of lead colic was not prominent until massive dosage with lead was adopted, and that no remedy seemed effective for its relief.<sup>22</sup>

This tonic rise is, I believe, comparable with lead colic because it takes the form of a temporary spasm lasting ten to thirty minutes, after which normal tone and movements may recur. It arises usually when the amount of soluble lead proved chemically in solution in Tyrode's fluid containing bicarbonate is between 1 in 16,000 and 1 in 12,000, and occurs regularly with 1 in 15,000 lead in Tyrode's fluid without bicarbonate; but, in the human jejunum, sheep intestine, and occasionally in young rabbits and hares, the tonic phase has occurred with 1 in 90,000 lead ion, so that certain species and young animals seem more susceptible. The analyses of Aub and his co-workers<sup>23</sup> show that in an unusual case the concentration of lead in the liver may be as much as 1 in 20,000, while the skeleton in an average of seven cases contained 1 in 16,000. These figures show that the concentration 1 in 90,000 capable of causing a tonic type of contraction in the human jejunum may exist in the human body, and the occurrence of intermittent attacks of colic merely requires the assumption of the mobilization of a portion of that stored in the bone and other tissues—probably as colloidal phosphate, as both Lewis and Aub have shown; this mobilization is facilitated by any increase in the H-ion concentration of the tissues which augments the solubility of the lead, as the analytical results have proved, and as Aub and his co-workers have demonstrated with greater detail and accuracy.<sup>27</sup>

We may now with some confidence explain lead constipation and colic. The constipation results from diminution or inhibition of the pendulum movements produced by small amounts of lead, and the consequent delayed transmission of the contents permits greater absorption of water and inspissation. If the lead salt be introduced by the mouth its astringent action will be contributory, and is probably the main effect in its therapeutic application. The

intermittent colic arises from increased tone of the intestinal muscle produced by lead ion in concentrations above 1 in 90,000, and is probably attributable to mobilization of lead from the storage tissues by intercurrent increase in the H-ion concentration of the blood. It has been shown that in mild cases only are nitrites or adrenaline of value during the attack.

Before leaving this subject I should point out that other metals have also been tested. Zinc inhibits intestinal contractions;<sup>21</sup> copper inhibits and then causes a tone rise like lead; thallium slows and weakens the rhythmic movements; beryllium inhibits movements and causes a slight tone rise; thorium inhibits for a brief period, and then slow, irregular contractions reappear. The inhibitory phase may be developed by excess of calcium or magnesium, but not by strontium or barium.

#### Action on the Uterus.

The action on the isolated uterus is essentially similar to that on the intestine; it has been tested on the guinea-pig, rabbit, rat, and human uteri—the last in strips from pregnant and non-pregnant uteri at various ages obtained at hysterectomies and Caesarean sections. Lead causes a weakening or cessation of the rhythmic movements with or without fall in tone level and, after an interval of from ten to fifteen minutes, stronger solutions cause a powerful tone rise succeeded by a fall when normal contractions may resume. Since the effects on the uterus are the same in all the animals tested, the action, having regard to the variation in uterine response to adrenaline, must be peripheral to the nervous control. The uterine muscle, even in the same species, varies in its sensitiveness to lead, weak anaemic uteri being particularly easily influenced. The inhibitory phase—and slight forms of the tonic phase—have been produced by 1 in 150,000 lead ion as nitrate. A moderate tonic phase frequently follows in guinea-pigs and rats from 1 in 15,000 lead ion in Tyrode's fluid with bicarbonate (chemically estimated in solution 1 in 90,000), but, in the uterus of the rabbit and human subject, the true tonic contraction rarely occurs before 0.5 c.cm. of N/1 lead salt has been added to Tyrode's fluid with bicarbonate. This is estimated chemically to produce 1 in 16,000 lead ion in solution—the same concentration which causes tonic contraction of the intestine. As regards colloidal preparations, the partly colloidal lead iodide was inhibitory in dilution of 1 in 15,000 lead ion, and caused a tonic rise in strength of 1 in 7,000 lead ion, while the true colloidal lead produces tonic effects in concentration of 1 in 3,750 lead ion, its inhibitory effects being less marked than those of soluble lead salts. The figures found by colorimetric analyses are illustrative but not yet final.

It is impossible to discuss here the influence of other drugs on the action of lead on the uterus. Suffice to say that lead can relax pituitrin tone and then produce its own tone, which can sometimes be relaxed by adrenaline, while adrenaline can contract the rabbit uterus after lead has relaxed it, and yet lead at first can relax the adrenaline contraction in this uterus. The problem is complicated, but the inhibitory action of lead seems to be on some controlling mechanism intimately associated with the muscle itself; the essential is that excessive doses of nitrites only will relax a lead tonus in the human uterus.

In regard to the cause of lead abortion, I believe there are two factors in operation. The first is the unusual toxic action of lead on embryonic cells, which has been reviewed. The second is the production of tonic contractions of the uterus, which is probably a more important factor in the causation of premature labour and stillbirths amongst lead workers.

#### Action of Colloidal Lead Injections.

The effects of injecting 5 c.cm. of a 0.5 per cent. colloidal lead preparation intravenously in rabbits are practically none; there may be a little acceleration of respiration, but nothing beyond this with a reliable preparation. All colloids are, however, not equally safe—one tested recently, for example, in this dose was fatal in thirty minutes, the toxic symptoms commencing after fifteen minutes with paresis and ending with respiratory failure.

Direct evidence of the immediate effects in animals is afforded by injections into cats under ether anaesthesia.

The action is very transitory, even with large doses introduced rapidly into the jugular vein. Usually within five to fifteen seconds from the start of the injection there is acceleration and often increased depth of respiration, a marked acceleration of the pulse for five to ten seconds, followed by a drop in the pulse rate to the normal, or more often below it. The blood pressure may show a transient rise, succeeded by a fall of from 20 to 25 mm. for a 5 c.cm. injection. These changes occupy no more than two to five minutes, at the end of which time respiration and pulse are again normal and the blood pressure is normal or somewhat lower. Repeated injections of 5 c.cm. accentuate the phenomena, but recovery is always rapid except in the case of the blood pressure. Decided evidence of a weakening in the force of the pulse tracing was confirmed by direct records of the auricular and ventricular contractions, which show that the auricular beats are for a few seconds very decidedly weakened or rendered irregular in force, while the force of the ventricular beat is also reduced, but the rhythm, though quicker, remains regular. In one animal having an excessively rapid heart beat with occasional extrasystoles the injections did produce irregularity in the rhythm. These cardiac effects are quite transient; even with intrajugular injections of 20 c.cm. the period of cardiac weakness lasts only from thirty seconds to a minute.

The preliminary rise in blood pressure is due to the pulse acceleration, the fall in blood pressure partly to the subsequent slowing of the heart rate and partly to relaxation of the arteries, because the two effects are not synchronous. The acceleration in respiration seems to be reflex from the fall in blood pressure. There has been very little evidence of increased general blood pressure in these experiments, although lead salts do contract isolated arteries.

In conclusion, pharmacological tests have shown that the lead suspension prepared in Professor Lewis's laboratories is quite safe for intravenous administration; but, having regard to what I have noted of the immediate action of lead on the heart, I should advise slow injections in cases where there is any cardiac disorder or renal disease. If this preparation can be successfully stabilized to permit of commercial distribution, it will be a safe therapeutical material for the purpose required.

## THE ACTION OF COLLOIDAL LEAD ON ANIMAL TUMOURS.

BY

FRANCIS CARTER WOOD, M.D.,

Director of the Institute of Cancer Research, Columbia University, New York.

WHILE the therapeutic capacity of colloidal lead as regards human tumours has already been established by Professor Blair Bell, there are many problems connected with the use of so dangerous an agent which can best be attacked by studying the action of the material on animal tumours. A considerable series of such experiments have been undertaken in collaboration with Professor Blair Bell and his colleagues of the Liverpool Cancer Committee. The facts presented to-day will concern only the changes which are observed in the tumours and organs of white rats. The tumours employed are transplanted, not primary. One is a carcinoma, two are sarcomata. They are highly virulent, growing rapidly to one-twentieth or even one-tenth of the weight of the host. The animals used were all of the same strain and of approximately the same age and weight, 60 grams. Preliminary tests showed that an animal of this size could bear between 2 and 4 mg. of freshly prepared colloidal lead intravenously. After twenty-four hours the suspensions became more toxic; no difference could be noted in the action on the tumours between a large less toxic dose and a small highly toxic one. The total number of tumour animals treated was about nine hundred.

A short time after the injection of a sublethal dose of lead the tumour becomes intensely congested, and later oedematous. This change is due to the thrombosis of a certain number of vessels in the tumour. This is followed by the necrosis of a large part of the growth, often leaving only a thin shell of tumour cells enclosing a haemorrhagic sac. In a few instances the tumours went on to final absorption; but in general recurrence takes place after a longer or shorter time, despite the administration of sublethal doses of lead. Evidently the action observed is predominantly due to the thrombosis, and only to a secondary degree to the direct toxic action on the tumour cell. No thrombosis is observable in the lungs or other organs, unless we assume that the focal necroses found in the liver are due to such a change. After large and repeated treatments the liver may show extensive lesions, the spleen and bone marrow atrophy, with the production of an intense anaemia. The kidney of the rat seems to be less susceptible to lead, and severe lesions are only found after large doses.

The application to human pathology of the results so far obtained is not easy. The tumours are very large in size in proportion to the host, corresponding to a human tumour of 10 to 30 lb. in weight—a manifestly incurable condition in man, so that the infrequency of cure in the animals is not astonishing. Nor can it be assumed that the extensive thromboses are so frequent in human tumours. The pain which follows the treatment in man may, however, be due to a more limited process of the same sort.

The experiments are being continued on smaller tumours, and as far as can be judged from preliminary observations the thrombosis plays a more subordinate part. So far it may safely be concluded that colloidal lead in sublethal doses produces profound changes in animal tumours which in a small percentage may lead to a permanent cure; and that, moreover, the necessary dose also induces serious but not irreparable changes in the liver and blood-forming organs. The steps in the process seem to be as follows. The lead is rapidly removed from the circulation, being absorbed by and in consequence damaging the capillary endothelium, and chiefly in the tumour. Thrombosis follows in the tumour only; the lead thus fixed in the neoplasm then exerts its toxic action on the neoplastic tissues.

[The above remarks on the action of colloidal lead on animal tumours, by Dr. Francis Carter Wood, are an abstract of a paper the full text of which is published in the *Journal of the American Medical Association*, 1926, lxxxvii, p. 717.]

## OBSERVATIONS ON THE HISTOLOGICAL CHANGES FOUND IN CANCEROUS TISSUES TREATED WITH COLLOIDAL LEAD SUSPENSION.

(With Special Plate.)

BY

ERNEST E. GLYNN, M.D., F.R.C.P.,

Professor of Pathology, University of Liverpool.

### INTRODUCTION.

At first sight it appears easy to decide whether the colloidal lead treatment produces histological changes in the malignant growths of man. In reality it is very difficult, for reasons which will be given later.

According to Blair Bell, Hendry, and Annett,<sup>1</sup> non-lethal doses of lead suspensions administered to pregnant does produce abortion by causing coagulation necrosis of the trophoblast. This necrosis apparently develops within two or three days. Lead, when given in sufficient initial quantities, probably produces abortion in the human female in about the same time; exact data are clearly difficult to obtain.

Carter Wood<sup>2</sup> has found that the malignant tumours of his rats necrosed in two or three days after the intravenous injection of lead suspensions.

Most human patients with malignant disease complain of pain in the region of the neoplasm within a few hours of the intravenous injection; this pain may last three or four days. Temporary increase in the size of malignant nodules and glands may also occur in the first two or three days. Rapid diminution, which is sometimes observed, begins a little later, and is most marked in the first ten days. Thus the most favourable time to examine malignant tissues treated with lead, for histological evidence of regression, as necrosis or degeneration, seems to be within the first fortnight of the last injection.

The recognition of such changes in tissues removed several months after the last dose of lead should be much more difficult, because one would expect the damaged cells to disappear; the disappearance should, however, be associated with some degree of inflammatory reaction, and finally with replacement fibrosis.

There is another and a more serious difficulty. Regressive changes are a characteristic of untreated malignant neoplasms; they include atrophy, oedema, fatty metamorphosis, hyaline or myxomatous degeneration, etc. Necrosis, haemorrhage, and thrombosis, and various degrees of inflammation from slight lymphocytic infiltration to suppuration and ulceration; and lastly fibrosis, also occur. The same microscopical section of a malignant neoplasm frequently shows histological evidence of progression in one portion and retrogression in another.

### METHOD OF INVESTIGATION.

Portions of the growth were selected and removed by Professor Blair Bell or one of his assistants, and haematoxylin and eosin sections were prepared in the Department of Obstetrics and Gynaecology. These sections were sent to me for examination and report. Comparison was then made between the histological appearances before and after treatment—no patient received lead unless the clinical diagnosis of malignancy had been confirmed by the microscope. Special attention was paid to the clinical history, also the number of days elapsing between the administration of lead and the removal of the growth, the amount of lead in the last dose, and the total administered from the beginning.

It was necessary to omit from this investigation the following:

1. Cases in which, for various reasons, it was impossible to obtain tissues for study after treatment. Thus, in Mrs. B. the tumour disappeared. "The patient, a woman aged 60, was very ill with advanced cancer of the cervix—verified microscopically. Hysterectomy was performed on July 18th, 1925, but a considerable amount of the growth was left behind. This gradually disappeared, and there is now (August, 1926) nothing abnormal to be found. The patient is in excellent health. She has received 0.61 gram of lead."

2. Cases in which the last dose of lead was administered many months before the tissue examined was removed, or the doses had been very small.

3. Cases treated with radium or x rays as well as lead.

4. Cases in which the effects of lead on the neoplasm have already been discussed by Blair Bell.<sup>2</sup>

The results of the investigation were negative in the majority of cases so far examined; but in the six summarized below there is some evidence that lead has produced histological changes. The histories have been furnished from the patients' case-sheets. The photomicrographs, taken by me and my assistant (D. K.), have been selected to give as faithful a representation as possible of the essential features of the section.

#### CASE 1.

H. A., male, aged 46. Cancer of the right breast of about seventeen months' duration. Excised April 16th, 1926; the subcutaneous skin graft did not take. Lead treatment begun April 21st. The total administered in eighteen days was 0.175 gram, the last dose of 0.075 gram being received eleven days before death. The lead produced no albuminuria and only slight stippling of the erythrocytes. On May 5th pyrexia began, followed by cough and dyspnoea. The patient died on May 9th.

*Post-mortem Examination* (thirty hours after death).—A granulating area marked the site of the excised breast; the edges of the wound were healing. There was bilateral acute diffuse pleurisy; the right pleural cavity contained a pint and a half of semi-purulent fluid. The spleen (weight 12 oz.) was diffident. The liver (weight 61 oz.) was rather soft and pale. It contained about eighteen small homogeneous yellowish-white metastases; those on the surface, from one-eighth to half an inch in diameter, were quite flat; there was no umbilication. Some metastases were present in both adrenals and on the surface of the upper lobe of the left lung—the latter were also flat. One enlarged gland was found at the insertion of the right pectoralis major. Specimens from this case are in the museum of the Pathological Department.

*Section 1, of the primary growth.*—This was an ordinary spheroidal-celled cancer, medullary type. The nuclei, which measured from 8  $\mu$  to 12  $\mu$ , were round and possessed the usual nucleolus (Fig. 3); mitoses were moderately numerous.

*Section 2, of liver with two metastases* (the larger measures 1 cm. by 0.3 cm.).—The appearance of the metastases is remarkable. The epithelial nature of the majority of the cancer cells is unrecognizable; they are spindle-, oat-, or even star-shaped, rather like those of a badly preserved sarcoma or myxoma. Their size varies greatly—from about 10  $\mu$  to 40  $\mu$  in length. Many are obviously dead, some are "ghosts" on the verge of disappearance (Figs. 1, 2, and 4). Few, if any, are "healthy" with round nuclei, also nucleoli, like those in the primary growth before treatment—or in parts of the infected pectoral gland after treatment (see Fig. 6, section 5). Some of the epithelial cells, less shrunken than the majority, are still arranged in cancer acini (Fig. 1, A); various transitions occur between them and the "sarcoma-like" cells and the ghosts—this is confirmed by their staining with van Gieson. The nuclei measure from 2  $\mu$  to 3  $\mu$  transversely and 4  $\mu$  to 5  $\mu$  longitudinally. The chromatin is condensed, and definite towards the centre of the nucleus. Mitoses are very rare; only two were found in the whole section. The edge of the liver (Fig. 2). The small local exudates of lymphocytes are the only evidence of inflammatory reaction. The blood vessels are normal; there is no thrombosis. The liver shows considerable cloudy swelling, also a little fatty degeneration of the inner part of the lobules. The fat is deposited in small and medium droplets around a central nucleus. Cytolysis is present in the centre of some lobules. There is no haemosiderin.

*Section 3, of lung with two metastases* (the larger measures 0.8 cm. by 0.4 cm.). *Section 4, of the suprarenal with a metastasis* (the latter measures 0.5 cm. by 0.2 cm.).—The appearance of the metastases in both sections is practically identical with that of the liver metastases; no healthy spheroidal cells like those in the primary growth were discovered.

*Section 5, of pectoral lymph gland* (measures 1.2 cm. by 0.8 cm.).—This consists of regenerating loose connective tissue, containing scattered epithelial cells in various stages of regression (Fig. 5); many of the latter resemble exactly those in sections 1 to 4, while others are indistinguishable from connective tissue. It is noteworthy, however, that some of the epithelial cells appear healthy (Fig. 5, D). A few, definitely spheroidal, cells are grouped in acini like those of the primary growth (Fig. 6). Even mitoses are present (Fig. 6, B).

The remarkable histological appearances of the five metastases in the liver, lung, and suprarenal are unlike anything hitherto observed by the writer. Autolysis cannot possibly account for them; the body was undecomposed, for the weather was cold and the *post-mortem* examination took place thirty hours after death. The appearances must be chiefly, if not wholly, due to the action of lead—it is possible that the associated sepsis may have contributed in some obscure way. Their occurrence within eighteen days of the first dose is consistent with the clinical observation already alluded to—namely, that

the most favourable time to find histological evidence of regression should be within the first fortnight of the last injection.

The "sarcoma-like" change in the epithelial cells is not due to polymorphism, described by various writers—recently by Kettle<sup>3</sup> in cancer of the breast, and Dawson<sup>4</sup> in melanomata. Polymorphism could not develop in a few days; besides, in this case almost every cell is similarly affected. The change signifies degeneration or death; this is indicated by the shrinkage of the cytoplasm and nuclear pyknosis. It explains why a liver metastasis, measuring half an inch in diameter on the surface, was neither raised nor umbilicated as usual.

The change has affected to a greater or less degree nearly all, if not all, the epithelial cells in the five metastases. The same change was present in the lymphatic gland, but less marked. Some cells appeared "healthy," while a few were grouped in acini, like those in the primary growth. Even mitoses occurred.

This striking histological contrast in the two localities is most important. It is evidence that the extent of the regression chiefly depends upon a well developed and unobstructed blood supply, and perhaps lymph supply. Now the blood supply of the liver, lung, and suprarenal is unusually free, and there was no fibrosis of the metastases in these organs. On the other hand, lymphatic glands are much less vascular; further, the fibrosis was so extensive in the pectoral gland examined that some of it must have been present before treatment, and therefore have obstructed the entrance of the lead.

The cloudy swelling and fatty degeneration of the liver is due to the sepsis and to the lead. In my experience a fatty change is usual in the liver of lead-treated patients; in some haemosiderin is also present. Dr. Dilling's experiments of injecting intravenously large doses of lead suspensions into cats are interesting in this connexion; for it has been found in Professor Lewis's laboratory that at least 40 per cent. of the lead was deposited in the cat's liver within two hours of the injection. (Details will be published in a subsequent paper.)

Lastly, it must be pointed out that this is the only case of lead-treated cancer, with metastases in other organs besides the lymphatic glands, which has so far come to *post-mortem* in Liverpool. The importance of investigating similar cases is obvious, especially in view of the associated sepsis in the one just described.

#### CASE II.

M. E., a woman aged 36, with cancer of the left breast. First seen November 3rd, 1920. "Lump noticed for twelve months"; it rapidly increased to the size of an orange, and then ulcerated through the skin (see photograph, Blair Bell<sup>5</sup>). The axillary glands were enlarged. A child was born on October 27th, 1920. A piece of breast was excised for examination on November 3rd. Lead treatment was begun on November 9th; the total amount received being 0.32 gram in forty-one days. The tumour and glands rapidly disappeared, but the patient nearly died of lead poisoning. A piece of the hardest part of the left breast was excised on December 25th, 1920, five days after the last dose of 0.04 gram of lead.

Present condition (July 20th, 1926): the patient is quite well; she has had two more children, which she suckled from the previously affected breast. Lead treatment has been stopped since December 20th, 1920.

*Section 1, of breast before treatment* (measures 2 cm. by 0.5 cm.).—The central and larger portion shows spheroidal-celled cancer, medullary type; the stroma is very scanty. The cell outlines are ill defined, the cytoplasm clear and finely reticulated. The nuclei are sometimes oval with a nucleolus and then measure about 7  $\mu$  by 10  $\mu$ , others are more irregular (Fig. 7); mitoses are present, but very rare. There is a little local lymphocytic infiltration, but no necrosis or other regressive change. The surface of the growth is ulcerated and covered with a layer of inflammatory tissue 1 to 2 mm. deep; the exudate is chiefly lymphocytic.

*Section 2, of breast after treatment* (measures 1 cm. by 0.4 cm.).—In one-third there are some normal breast acini with a few lymphocytes dispersed among them; in two-thirds there are no acini but a subacute diffuse interstitial inflammation which is rather less severe than that on the surface of section 1. The relative amount of lymphocytes and other inflammatory cells and connective tissue varies (Fig. 8). There is no trace of cancer.

So far as the writer is aware, no one who has examined section 1 has disputed the histological evidence of malignancy—the clinical evidence has already been alluded to. The unusual clearness of the cytoplasm and the ill defined outline of the epithelial cells may be explained by the occurrence of lactation. The histology is similar to that shown in a photograph of cancer in a lactating breast by

Greenough? (Case 47, Plato VI). The greater inflammatory reaction in the breast (forty-one days after treatment began) than in the liver metastases of Case 1 (eighteen days after treatment began) demands explanation. It is mainly due to a persistence of the original inflammation—for the growth was ulcerating. But the possible effect of the duration of treatment must be remembered.

CASE III: Diagram, from case sheet, of cancer recurrences a, b, c, d.

and (c) smaller" (June 1st, 1924). The site of nodule (b) was excised for examination on July 8th, forty-eight days after treatment had begun. The 0.19 gram—the last dose (0.02 gram) fourteen days before.

The patient died from abdominal metastases in November, 1925. She received between July 8th, 1924, when the nodule was excised, and April 29th, 1925, 0.58 gram of lead.

Section of nodule (b) fourteen days after treatment stopped (measures 0.9 cm. by 0.6 cm.).—It has been compared with sections of two subsequent subcutaneous recurrences from the same patient's breast removed on November 19th, 1924, also with a section of the skin of the breast of another woman about the same age. The epidermis is normal. The papillary layer of the corium is very loose for about 0.5 mm. below it throughout the whole length of the section; the elastic fibres stained with orcein are unusually conspicuous. The reticular layer is normal. The subcutaneous layer is unusually fibrotic for a depth of 4 mm.; below this there is normal subcutaneous fat.

The loose papillary layer may be due to previous stretching by a metastasis, which has subsequently disappeared.

The fibrotic subcutaneous tissue may be due to the persistence of a cancerous stroma after the epithelial cells have disappeared. This view is supported by the appearance of the two recurrences; for the deepest layers show a typical well developed scirrhous cancer, but as the corium is approached the epithelial cells gradually atrophy and finally become unrecognizable, so that the upper layer resembles exactly that in nodule (b). On the other hand, W. S. Handley<sup>3</sup> has pointed out that "the disappearance of malignant nodules has repeatedly been observed by various surgeons. Short of total disappearance, such nodules may shrink up, and may be found on section to consist entirely of fibrous tissue."

#### CASE IV.

E. H., a woman aged 48, with cancer of the ovary. Symptoms were first noticed in January, 1924; later there was emaciation and ascites. Laparotomy was performed on March 14th, 1925, and a large, cystic, extensively adherent, malignant tumour of the left ovary found. The greater part was removed, with the uterus and both appendages. Subsequently, on January 2nd, 1926, a lump the size of a pigeon's egg was felt in the pouch of Douglas—evidently from piece dropped at operation. Part of this was excised on January 11th, the remainder being adherent to the

rectum. Lead treatment was begun March 25th, 1925. The total lead received was 0.6 gram, the last dose (0.05 gram) being administered on August 21st, 1925—143 days before the second operation.

Present condition (August 10th, 1926): the patient is quite well; she has gained several stones; there is no tumour in the pouch of Douglas, and no recurrence. She has received—between January 11th, 1926, when the lump was excised, and June 22nd—0.3 gram of lead.

Sections 1 and 2 before treatment (measured 1.25 cm. by 1 cm. and 0.8 cm. by 1 cm.).—Both show a cystic adenocarcinoma which is proliferating irregularly; in some parts the epithelium is atypical, two or more layers are present, or the basement membrane is penetrated. One part is becoming solid. No mitoses were seen (Fig. 9). About one-quarter of the epithelial cells in section 2 contain more or less secretion, but definite goblet cells are exceedingly rare. Secretion is occasionally present in the lumen. The stroma is loose, the number of connective tissue cell nuclei being relatively few (Fig. 9). There is very slight inflammatory reaction and no necrosis or other regressive changes.

Sections 3 and 4 after treatment (measures 2.1 by 1.4 cm. and 1.8 by 0.5 cm.).—The greater part of both sections show an ordinary pseudo-mucinous cyst-adenoma, and no evidence of malignancy. The lumina contained much secretion, for goblet cells have developed in three-fourths of the epithelium in one section and in one-third of the other (Fig. 10). Some acini contain little epithelial lining. At the periphery of the growth the acini are also regressing; in one the epithelium is polymorphic, degenerating and almost unrecognizable—though its origin is proved by the presence of mucin in two cells (Fig. 11, C). The outer cells are specially degenerate; they gradually fade into the surrounding stroma. Another regressing acinus is shown in Fig. 12; the stroma is denser and more fibrous than in sections 1 and 2 and connective tissue nuclei are relatively more numerous.

The clinical history, macroscopic and microscopic appearances of the primary growth, indicate that it was a cystic adenocarcinoma. The degeneration and absorption of the epithelium at the periphery of the nodule removed after treatment, also the very extensive development of goblet cells, are consistent with the diminution of malignancy, or perhaps with the disappearance of malignancy, suggested by the clinical history.

#### CASE V.

E. M., a woman aged 54, with cancer of the body of the uterus, verified microscopically. She was seen on November 25th, 1924, and stated that she had had haemorrhage for two months. The uterus, tubes, and ovaries were removed on December 15th, 1924. Several malignant nodules were present in the vaginal wall near the orifice, the largest being about half an inch in diameter. A small nodule was removed for examination; the others were left. Lead treatment was begun on December 31st, 1924. The vaginal nodules diminished to at least half their original size by January 28th, 1926, when one was removed for examination. The total lead received in 361 days was 0.77 gram—the last dose (0.075 gram) sixty-six days before removal of the nodule.

Present condition (August 7th, 1926): The patient is quite well; the vaginal nodules have disappeared. She subsequently received between January 28th, when the nodule was removed, and August 7th 0.075 gram of lead.

Section 1, of vaginal nodule before treatment (measured 1.5 cm. by 1 cm.).—In the deeper part of the vaginal wall, about 3 mm. below the surface epithelium, there is an area 5 mm. in diameter of an atypical infiltrating columnar-celled cancer; parts are almost solid. Mitoses are absent, regression is slight. The growth exactly resembles that in the uterus.

Section 2, of vaginal nodule after treatment (measures 1 cm. by 0.25 cm.).—It contains three small isolated acini of columnar cancer, the largest being 0.75 mm.; each acinus is dilated, and less solid than in section 1; the stroma is more inflammatory.

#### DESCRIPTION OF SPECIAL PLATE.

FIG. 1.—Case I. Liver metastasis of spheroidal-celled cancer after treatment; showing the ill formed acini of shrunken cancer (A). (× 320.)

FIG. 2.—Case I. Liver metastasis of spheroidal-celled cancer after treatment; showing the "sarcoma-like" and degenerated cancer cells, also the fatty degeneration of the liver. (× 190.)

FIG. 3.—Case I. Spheroidal-celled cancer before treatment; showing primary growth in breast. (× 750.)

FIG. 4.—Case I. Liver metastasis of spheroidal-celled cancer after treatment; showing the "sarcoma-like" cancer cells and "ghosts," also the nuclear pyknosis. (× 750.)

FIG. 5.—Case I. Pectoral lymphatic gland metastasis of spheroidal-celled cancer after treatment; showing less regressive change than in the liver metastasis, also one "healthy" cancer cell (D). (× 750.)

FIG. 6.—Case I. Pectoral lymphatic gland metastasis of spheroidal-celled cancer after treatment; showing cluster of "healthy" cancer cells and a mitosis, resembling those in primary growth before treatment (Fig. 3). (× 750.)

FIG. 7.—Case II. Ulcerating spheroidal-celled cancer in lactating breast before treatment; showing the cancer and a few inflammatory cells. (× 190.)

FIG. 8.—Case II. Ulcerating spheroidal-celled cancer in lactating breast after treatment; showing interstitial inflammation and absence of cancer cells. (× 190.)

FIG. 9.—Case IV. Cancer of ovary before treatment. (× 200.)

FIG. 10.—Case IV. Cancer of ovary after treatment; showing growth in the pouch of Douglas (which subsequently disappeared). Note the very numerous goblet cells. (× 200.)

FIG. 11.—Case IV. Cancer of ovary after treatment; showing a regressing acinus at the edge of growth in the pouch of Douglas (which subsequently disappeared). Note the mucin in two cells (C). (× 170.)

FIG. 12.—Case IV. Cancer of ovary after treatment; showing a regressing acinus at the edge of the growth in the pouch of Douglas. (× 170.)

FIG. 13.—Case VI. Cancer of the breast: axillary gland before treatment; showing large mass of cancer and little stroma. (× 100.)

FIG. 14.—Case VI. Cancer of breast: supraclavicular gland after treatment; showing small islets of cancer and much stroma. (× 100.)

W. BLAIR BELL: MALIGNANT NEOPLASMS: THEIR TREATMENT BY LEAD.

[THE BRITISH  
MEDICAL JOURNAL]

FIG. 1.—The left half of the illustration shows normal trophoblast in the blood vessel. (Photomicrograph  $\times 400$ .) The right half shows a mass of syncytial cells in the human lung. (Section kindly lent by Mr. J. G. Storer.) (Photomicrograph  $\times 170$ .)

FIG. 2.—Section of carcinoma of breast, showing syncytial arrangement of the cells. (Photomicrograph  $\times 100$ .)

FIG. 3.—The same as Fig. 2 under higher magnification. (Photomicrograph  $\times 460$ .)

FIG. 4.—Section of sarcoma of ovary, showing so-called "giant cell," in reality a syncytial arrangement of cells. (Photomicrograph  $\times 500$ .)

FIG. 5.—Section showing convolutions of trophoblast in the rabbit in which coagulation necrosis has been produced by lead. The maternal cells are unaltered. (Photomicrograph  $\times 160$ .)

FIG. 6.—The same as Fig. 5 under higher magnification. (Photomicrograph  $\times 225$ .)

The histological change in the neoplasm after treatment is rather less marked than one would expect in view of the diminution of malignancy, or perhaps disappearance of malignancy, suggested by the clinical history.

#### CASE VI.

M. D., a woman aged 70, with cancer of the breast—"noticed one year." A radical operation was performed on October 20th, 1923. Lead treatment was begun on November 5th, 1923. Enlarged supraclavicular gland first observed and excised on July 21st, 1925. The total lead administered in the 623 days was 0.55 gram, the last dose (0.01 gram) being seventy-four days before gland excision.

Present condition (September 25th, 1926): The patient subsequently received, after the gland excision, 0.69 gram of lead, the last dose (0.1 gram) being on February 16th, 1926; at this date the right arm was swollen, "but had been more so." The arm is now so swollen that the patient is bedridden; there are two small subcutaneous recurrences.

Section 1, of axillary gland before treatment (measured 1.1 cm. by 0.7 cm.).—Five-sixths are completely infiltrated with medullary type of spheroidal-celled cancer; very scanty stroma and practically no regression (Fig. 13). Mitoses are moderately numerous, maximum number in a 1/6 in. field four or five.

Section 2, of supraclavicular gland after treatment (measures 1.2 cm. by 0.8 cm.).—It is infiltrated with scirrhous cancer; stroma unusually extensive, especially in the centre (Fig. 14). Nevertheless, there are many areas of apparently actively growing cancer, though mitoses are very rare. Towards the peripheral third of the section the cancer cells are increasingly distorted and atrophied; they finally become unrecognizable.

The gland removed after lead treatment shows very extensive and definite regressive changes, and is a striking contrast to the gland removed before treatment. On the other hand, it must be remembered that in lymphatic glands "evidences of retardation" of cancerous "growth" by fibrosis and encapsulation are relatively common" (Ewing).<sup>9</sup> The areas of actively growing cancer also present in the gland are consistent with the development of the recurrence, and of oedema of the arm, while the patient was still under treatment.

#### SUMMARY AND CONCLUSIONS.

This investigation is proceeding; still, the following tentative conclusions have been drawn.

1. In the majority of lead-treated malignant growths so far examined no histological evidence of its action could be detected.

2. In a case of ulcerating cancer of the lactating breast the cancer cells disappeared. In certain other cases of cancer there was histological evidence that lead had increased the regressive changes which usually occur in malignant neoplasms, and in one that it had slowed the rate of growth and so allowed the epithelium to become more differentiated.

3. In another case of cancer of the breast dying from sepsis, remarkable regression of the epithelial cells occurred in metastases examined from the liver, lung and supra-renal; this was less advanced in a metastasis from a fibrosed lymphatic gland, for some of the unaffected epithelial cells even showed mitoses. The changes were chiefly, if not wholly, due to the lead—it is possible that the associated sepsis may have contributed in some obscure way.

The lesser degree of regression in the relatively avascular, also, fibrosed lymphatic gland indicates that the action of lead chiefly depends upon a well developed and unobstructed blood supply and perhaps lymph supply. It is histological evidence of an inherent difficulty in treating cancer by lead or by any other drug or by serum. It must be remembered, however, that success or failure of lead treatment may perhaps sometimes depend upon idiosyncrasy of the patient, as in other diseases treated with other drugs.

## THE CLINICAL EFFECTS OF LEAD IN THE TREATMENT OF MALIGNANT DISEASE.

BY

L. CUNNINGHAM, M.B.CAMB., M.R.C.P.LOND.,  
Honorary Assistant Physician, David Lewis Northern Hospital,  
Liverpool; Assistant Director, Liverpool Cancer  
Research Organization.

#### SELECTION OF CASES.

In treating malignant disease with lead one of the greatest difficulties with which we have had to contend has been the selection of those cases which present a reasonable chance of being benefited and which at the same time are likely to withstand the toxic effects of the therapeutic agent employed. There are, of course, certain obvious contraindications to treatment, among which must be mentioned gross pathological lesions of one or more important organs of the body, and serious cachexia of the patient. We have been brought face to face, however, with another problem, namely, the idiosyncrasy of the individual, which unfortunately discounts to a certain degree the investigations of the vital functions of the body, upon which, nevertheless, we lay considerable stress. We are unable to explain how it is that, other things being equal, some patients, for no apparent reason, are unaffected by large doses of lead, whereas others are made very ill, and may even die after a moderate dose.

It has been our practice before undertaking the treatment of cases to make a complete analysis of the blood and urine, apart from the careful medical examination of the important organs of the body. We also make use of radiological studies where these are likely to be of assistance in diagnosis and in determining the extent of the disease. These investigations are carried out from time to time in the course of treatment; in particular, observations are repeatedly made in regard to the blood and urine.

In the case of the blood, full counts are made of the red and white corpuscles, and the percentage of haemoglobin is estimated. The blood urea is also determined, and, in certain cases, the blood sugar. In the course of treatment we examine regularly blood films for stippling of the red cells, and this has been of great value in indicating, not only the dose of lead which should be given at any period, but also the interval which should be allowed to elapse before a further dose is given. We usually suspend treatment when there is more than one stippled cell per field, even in the absence of any other contraindication.

A complete analysis of the urine is made, and the simpler investigations of the renal function are also repeated from time to time. When there is reason to suspect liver involvement, a laevulose tolerance test may be performed.

#### TOXIC EFFECTS OF LEAD.

The administration of lead is usually accompanied by a certain amount of reaction. This reaction may be either focal, general, or both. The patients generally complain of pain at the site of the tumour a few hours after the injection has been given. The constitutional reaction of the patient is very variable, and will depend upon which organ, or system of the body, the injurious effect of lead is most manifest.

The toxic effects of lead, as already recorded,<sup>1</sup> have been observed, not only on the blood and blood-forming organs, but also on the gastro-intestinal system, the kidneys, the liver, and, to a lesser extent, on the central nervous system.

#### The Blood.

In the case of the blood all types of anaemia have been noted, varying from a grave secondary anaemia to the severest form of aplastic pernicious anaemia. We usually meet with the type in which the reduction of the haemoglobin is more marked than the reduction in the red blood corpuscles count. Other changes noted have been polychromasia, anisocytosis, poikilocytosis, the appearance of abnormal forms, and punctate basophilia, to which reference has been made. The presence of nucleated red corpuscles is not very uncommon; when present they are invariably associated with considerable anaemia, and with stippling of the red corpuscles. Since the nucleated cells

themselves may be stippled, it appears that degenerative processes associated with the formation of stipples, whatever they may be, can occur at a very early stage in the life of the red cells.

The opinion of authorities is divided at the present day as to the exact nature of the stippling of the red corpuscles. We do not consider that it is a regenerative process, because stipple cells have not been found in the bone marrow of animals which have had lead injections. Neither do we consider that the stipples are the result of the disintegration of the nucleus, for we have observed nucleated red cells showing a perfectly well defined and well stained nucleus, which have also presented coarse punctate basophilia. Dr. Brookfield, working with us, considers from data obtained from comparative counts and special staining reactions that the stippling of the red cells is almost certainly due to a modification of the basophil material in the young red blood cells—namely, the polychromatophil cells and reticulocytes. This modification results in the precipitation of the basophil substance into the familiar discrete punctate granules.

It follows that with such marked blood destruction all the symptoms of anaemia may be present. Among these may be mentioned pallor of the skin and mucous membranes, headache, lassitude, and muscular weakness; oedema of the ankles may even occur without evidence of cardiac or renal involvement. In several of our patients the anaemia has been so great that a blood transfusion has been considered necessary before treatment could be continued.

The rate of recovery from anaemia is of interest. Recovery following large doses of lead is rapid; whereas the anaemia produced by small doses administered over a long period may be very protracted.

Variations in the white blood corpuscles are not nearly so characteristic as those in the red corpuscles and haemoglobin, but we have observed the following changes: leucocytosis, relative lymphocytosis, slight eosinophilia, and leucopenia.

#### *The Alimentary Tract.*

The signs and symptoms observed as the result of the effect of lead on the alimentary system are variable. The most important of these are a blue line on the gums, nausea and vomiting, intestinal colic, constipation, and diarrhoea. The appearance of the blue line has been comparatively rare, and we feel that this rarity is due to the method of administration, and that the blue line which has been observed in cases of industrial lead poisoning is due to the fact that the lead passes through the mouth on its way to the lungs or gastro-intestinal tract; moreover, the state of the teeth is of importance. It is sometimes observed that a patient complains of nausea and vomiting immediately after the injection. This is undoubtedly an anaphylactic phenomenon, and is due to the proteins which are present in the preparation. Usually, however, these symptoms are delayed for a few days; indeed, as much as a week may elapse before they appear. Intestinal colic, which we have only observed since the administration of large doses of lead, is usually of the delayed type. We have seen very few cases of constipation or diarrhoea which could be attributed to the effect of lead.

#### *The Kidneys.*

The kidneys are often involved early in the treatment. Recovery from kidney lesions which have been produced by large doses of lead is generally rapid, whereas small doses of lead administered over a long period are liable to produce permanent damage. As a rule, after the initial dose of lead, clinical manifestations are not apparent. Occasionally, however, diminution in the secretion of urine and oedema may occur, together with changes in the urine. Cessation of treatment for the time being has always followed the appearance of symptoms, or of other evidence of renal involvement, with the result that further signs of renal failure have not occurred. Pre-existing renal disease has been regarded as a contraindication to treatment, or as an indication for treatment by small doses, according to the severity of the disease. We have not found the blood urea of much value in determining the onset of renal disease in the course of treatment, but it has been useful in determining the degree

of renal damage in patients prior to treatment. We have, unfortunately, had two disasters in treating our cases, the lead producing a condition of renal failure associated with tubular necrosis. In these we have invariably found a large and steady rise in the blood urea. The urea-concentration test has only been of value in the selection of cases. Diminution in the secretion of urine often precedes the appearance of albumin, and affords a valuable indication of early renal damage. Albuminuria has occurred in 23 per cent. of cases treated.

We have investigated the blood pressure of patients before treatment was adopted, at varying periods during the course of treatment, and subsequent to treatment. We have found no tendency to a rise in blood pressure. The changes observed in regard to the blood pressure have been so slight that it is difficult to establish any effect which is likely to be directly attributable to the lead. On the one hand, progressive disease and advancing cachexia would tend to lower the blood pressure, and clinical improvement would have the reverse effect. The average systolic blood-pressure readings of patients before treatment and after a course during which more than 0.3 gram of lead has been administered are 132 mm. and 130 mm. respectively.

#### *The Liver.*

It is probable that many such symptoms as headache, rigors, nausea, and vomiting are due to the impairment of hepatic function. Wilcox<sup>2</sup> has pointed out that, in all cases of generalized poisoning, the liver is the first line of defence, and it absorbs most of the toxic agent from the blood stream. This has been proved to be the case after the administration of the arsenobenzol derivatives.

We have noted three types of jaundice in our cases. The first type is characterized by a slight icteric tinge of the sclerotics, associated with an increase of urobilin in the urine, and a positive indirect, or at least a delayed direct, van den Bergh reaction. The bile-secreting cells are probably unaffected, and the jaundice is due to the excessive production of bile pigments from the products of haemolysis by the Kupffer cells. These pigments are produced in too large a quantity to be taken up directly and secreted by the liver cells, with the result that a quantity continues to circulate in the blood, and slight jaundice follows—a similar state to that which occurs in pernicious anaemia and acholuric jaundice. In the second type there is apparently damage to the polygonal cells of the liver, for, in addition to the appearance of excessive urobilin in the urine, bile may also be present. The jaundice is deeper, and the van den Bergh reaction is biphasic, or of the direct type. In the third type of jaundice there is evidently a cholangitis in addition, perhaps, to the destruction of the polygonal cells of the liver. The jaundice is deeper, and a large amount of bile appears in the urine. There may or there may not be an increase in the urobilin of the urine, and the van den Bergh reaction is of the immediate direct type.

Lead thus appears to influence the bile-producing mechanism just like phosphorus, arseniurated hydrogen, and toluenylenediamine, partly through blood destruction, and partly through its direct effect on the bile-secreting cells of the liver.

An investigation has been made of the changes in regard to fragility of the corpuscles following an injection of lead, with a view to correlating this, if possible, with the blood destruction, and the appearance of an excess of urobilin in the urine. We have, however, been unable to detect any definite increase in the fragility of the corpuscles, even in the cases showing definite jaundice of the haemolytic type. There is perhaps a state of affairs produced similar in nature to that which occurs in pernicious anaemia, in which the fragility is either normal or slightly decreased.

#### *The Nervous System.*

Psychopathies may occur after the intravenous administration of lead, but are, however, rare.

Neuropathies had never been observed in any of our cases until recently, when we believe we saw our first case, in which there was paralysis of the lower limbs with loss of reflexes and absence of sensory changes. I shall refer to this case again.

We are now in a position to avoid all the more serious toxic effects of lead, although it is only to be expected that those of a less serious nature will occasionally be seen.

#### TREATMENT OF TOXIC SYMPTOMS.

In order to eliminate so far as possible the toxic effects of lead during treatment, we have always endeavoured to diminish the work of the kidney. The diet given is light, and all foods with a high protein content are restricted or forbidden. The patients are encouraged to drink two or three pints of imperial drink and barley water daily.

In treating anaemia we have made use of intramuscular injections of iron arsenite, supplemented when necessary by blood transfusion. Perhaps the most difficult symptoms to treat have been those associated with the gastro-intestinal system. Vomiting and colic in particular are often protracted. The former is frequently associated with ketosis, which tends to produce a vicious circle, and is greatly benefited by administration of glucose and insulin, together, when necessary, with salines. In the treatment of severe colic we have almost invariably had to resort to morphine and atropine. We hoped to find that sodium thiosulphate, administered intravenously, by rendering the lead salts insoluble might eliminate the toxic effects to a certain extent, but the results obtained are far from promising. Intravenous injections of a solution of calcium chloride (5 per cent.) appear, however, likely to prove beneficial.

#### The Method of Administration and Dosage.

The preparation of lead is almost invariably administered intravenously, as the best method of attacking malignant disease is obviously through the blood stream; this is undoubtedly the most rapid and inevitable way of reaching all the tissues of the body. To assist us in determining when the needle is in the vein we have made use of an "interceptor"; it is made of glass, and is fixed between the nozzle of the Record syringe and the needle. The surgeon is enabled thereby to see the ascent of blood when the vein is reached.

We have long used the method of ionization for the introduction of lead ions into superficial neoplasms. In certain cases where there is extensive lymphatic invasion, such as is seen in carcinoma of the breast, there may be a diminution in the pain and a softening of the parts. Dr. Annett, working with us, found that of all metals used for the ionization of rat sarcoma lead is by far the most effective. This has been fully confirmed by the work of Borrel,<sup>3</sup> Girard,<sup>4</sup> and others.

The dosage of lead naturally varies with the particular case under treatment; indeed, we are not yet satisfied that we are using the optimal dose, and are still experimenting in this respect. In the last six months, provided there were no untoward effects, we have given two doses of 20 c.cm. and two of 15 c.cm. of the 0.5 per cent. preparation, when possible at an interval of ten days between each dose. The patient is then given one month's rest. At the end of this time smaller doses, amounting to 10 c.cm., are given at varying intervals until the total of 120 c.cm.—that is, 0.6 gram of lead—is reached. In those cases where the tumour was of slow growth, and there was no great urgency for placing the patient under the influence of a large quantity of lead, we have given smaller doses from the first. In this way some of the more acute toxic effects have been avoided. This is a very important point, as many patients, having experienced these acute toxic effects, have refused further treatment. It appears that, provided there is time to administer the lead in this way, the ultimate effect may be as good as in those cases which have received the large doses. No definite correlation exists between the toxic effects of lead and the influence of this preparation on the malignant tumour. We naturally regard the case as being more favourable when the patient is able to tolerate the injections well.

#### RESULTS OF TREATMENT.

Up to last November, at the end of the first five-year period, 247 patients had been seen, and of these 227 received treatment. A complete account of these will be

found elsewhere.<sup>5</sup> In the current year our percentage of successes bears out our previous figures. Of these 227 patients, 50 have received benefit; they are either living normal lives, or the disease is completely arrested, or the disease is believed to be cured and treatment stopped. On the other hand, in the remaining cases we have met with failure. This latter group of cases may be viewed from two points: first, the lead had no action on the malignant growth present; secondly, our methods of treatment are imperfect. As there is little doubt that lead has a specific action on malignant neoplasia, it is probable that in some cases the lead failed to reach the growth in sufficient quantity to cause arrest or disappearance.

In some of the cases in which we failed to bring about the desired result many changes occurred in the growths which we regard as significant. Among these may be mentioned lobulation and the appearance of oedema. Some patients actually died as the result of the destructive action of lead on the growth.

It is impossible to define the cure of cancer. It is well known that the possession of a malignant growth successfully treated by surgical or other procedures does not confer immunity from subsequent development. Moreover, a malignant growth may develop on the site of a primary growth apparently successfully treated, or in the form of a metastasis very many years later. The five years' period, therefore, usually allotted to the demonstration of a cure is not valid. For this reason we think it proper to describe our patients who are now apparently well and give no evidence of disease, as "believed cured."

The fate of the 227 cases that were treated can best be made clear by a table already published.

#### Fate of Patients, November 9th, 1920, to November 9th, 1925.

|  |     |
|--|-----|
| Died before treatment could be completed   | 50  |
| Died of intercurrent affections  | 3   |
| Died after treatment (including two deaths from acute nephritis, the result of lead poisoning) | 106 |
| Died as a result of extensive destruction of growth by lead                                    | 4   |
| Too recent for results to be estimated   | 14  |
| Complete treatment refused, but patients are living normal lives                               | 9   |
| Disease completely arrested  | 10  |
| Believed cured, and treatment stopped  | 31  |

227

The most interesting groups are those in which the growth has been completely arrested, or the patient is believed to be cured, and it is to these groups that I particularly wish to draw your attention.

In the course of treatment we invoke the aid of surgery and the administration of x rays where either of these methods of treatment is likely to supplement the effects of lead. The cases, therefore, in which we claim successes fall into three groups: (1) Cases that were treated with injections of colloidal lead only; (2) cases that were treated with lead and x rays; (3) the group in which an incomplete operation was performed, but the cases were subsequently treated with lead.

I shall now read to you brief notes of a few illustrative cases in each group. Most, if not all, of these cases have been described previously. I recapitulate them, however, in order to complete my presentation of the clinical aspects of the subject.

The following were treated with lead alone.

*Case 34.*—This patient was a woman, aged 27, who, in November, 1922, was operated upon for intestinal obstruction. A growth in the small intestine was found and a lateral anastomosis was performed, no attempt being made to remove the tumour; but a small piece was removed for section, and this showed the growth to be a lymphosarcoma. She received 0.44 gram of lead. Her general condition is very good, and there is nothing abnormal in the abdomen. Subsequently (March 26th, 1925) a gynaecological operation was performed, when the site of the lesion in the small intestines was identified with difficulty.

*Case 50 R.*—This patient was a married woman, aged 55. She complained of irregular vaginal haemorrhage. On examination she was found to have three small nodules of the size of the vagina and an enlarged uterus. Hysterectomy was performed, and a portion of one of the vaginal nodules was removed for section. The growth in the uterus was found to be a columnar-celled carcinoma, and the piece of tissue removed from one of the vaginal nodules also proved to be adenocarcinomatous. She was treated, and in all received 0.52 gram of lead up to November, 1925. The masses in the vagina disappeared, and her general health is in every way satisfactory. It is now (July, 1926) eighteen months

since the treatment was commenced, and a section recently prepared from a piece of hard tissue on the site of one of the pre-existing nodules shows nothing but fibrous tissue.

**Case 1.**—This patient was a woman, aged 36, who was sent to us with a large fungating carcinoma of the left breast. It was attached to deeper structures, and there was a mass of glands in the axilla. Any operation was considered impracticable, but a portion of the edge of the ulcer was removed for section, and proved to be carcinoma. She received 0.32 gram of lead. The ulcer healed in a fortnight, and the whole tumour disappeared within six weeks. Subsequently a piece of breast tissue was removed, and histological examination showed fibrous tissues only. At present—nearly six years since the treatment commenced—the patient is quite well, and on palpation the breast appears to be normal. During this period she has had two babies, and has nursed them at this breast. She comes to see us periodically to report.

**Case 119.**—This patient was a woman, aged 50, who was first seen by us in July, 1923, when she had ascites and small nodules of adenocarcinoma in the liver and omentum. No primary growth was found. She had to be tapped each fortnight, and an average of 15 pints of fluid was withdrawn on each occasion. Subsequently she received 0.345 gram of lead. For the last twenty months the patient has been and looks very well. There is no sign of recurrence or of free fluid in the abdomen, and she is able to do her own housework.

**Case 129.**—A man, aged 68, came to us in an emaciated condition, having a few months previously had a gastrostomy performed subsequently to complete occlusion of the oesophagus by cancer. We have not a section of this case, but the Wassermann reaction was negative. He had been operated on by Mr. Thelwall Thomas, and was also seen by Mr. Somerville Hastings, both of whom had no doubt whatsoever of the nature of his disease, which was also demonstrated by x-ray examination. It is well known that few patients have ever lived more than nine months after gastrostomy in these circumstances, and even this period is rarely covered. This patient is still alive, two and a half years later, but changes are still taking place. He is anaemic as the result of haemorrhages from the oesophagus; only recently he was able to swallow for the first time.

The following cases illustrate the complete arrest of growth in the neoplasm without disappearance. The first is interesting also in that there is evidence of a lead neuropathy.

**Case 178.**—This patient was a woman, aged 38, who four months prior to admission complained of abdominal pain. A mass was discovered in the pelvis, and laparotomy was performed by a London surgeon, who found a very large vascular growth filling the whole of the pelvis and most of the lower part of the abdominal cavity. On account of the danger from haemorrhage no portion of the tumour was removed even for section. On admission there was a large soft central tumour extending above the umbilicus, irregular in outline and filling the pelvis. She came under our care in December, 1924. A further laparotomy was done, and a small piece removed for section. Examination proved the tumour to be a short spindle-celled sarcoma, probably arising in the ovary. She was given 0.15 gram of lead at one injection. This caused most distressing toxic symptoms, both gastro-intestinal and urinary. Vomiting persisted for over a fortnight. Twelve days after the injection the abdomen was quite flat and only a small lump could be felt above the pubis. We should have liked to give her a further injection, but in view of the very serious symptoms which developed after the first it was considered necessary to delay treatment for a considerable time, and during the latter part of this period the lump increased in size. She has had further treatment and a mass of moderate size is still palpable. Unfortunately, this patient has recently developed a lead encephalopathy, and is suffering from drowsiness, loss of memory, and inability to focus her attention. She has also developed paralysis of the lower limbs—the only case of neuropathy we have yet encountered. She has had no lead for some considerable time—that is, since March 5th, 1926—but the total quantity administered has been large (0.9 gram).

**Case 185.**—The patient was a woman, aged 20, who herself discovered a lump in the abdomen. She came under our observation in March, 1925, when a laparotomy was done. A large retroperitoneal sarcoma was found, which was too vascular to be incised; a lymph gland was removed for diagnostic purposes. This was subsequently reported by Professor Glynn to be sarcoma. Since that date she has had 0.75 gram of lead. Her general condition is very good. The tumour is considerably smaller, and is causing no symptoms; apparently growth has been completely arrested.

Of those treated with lead and x rays the following case is a good example.

**Case 140.**—The patient was a man, aged 34, with a large sarcoma of the scapula and a mass of glands in the axilla, one of which was removed for section and found to contain mixed-celled sarcoma. He was given 0.22 gram of lead and eighteen x-ray exposures, twice weekly, to the scapula only. In thirteen months the scapula was normal. Altogether he has had 0.24 gram of lead, the last injection being given over eighteen months ago. He is quite well, two years and three months later, and there is no abnormality whatever of the scapula. His general health is good and he is able to follow his employment.

The following three cases are examples of the type in which the operation was incomplete, and which were subsequently treated with lead, with a satisfactory result.

**Case 9c.**—A woman, aged 34, with malignant disease of the rectum. The rectum was excised, and the sigmoid brought down to the anal orifice, but a large mass of growth was left in the pelvis. Section showed it to be a typical columnar-celled carcinoma. Subsequently, she was given 0.265 gram of lead. She is now very well and has gained weight, and there is no evidence of malignant disease.

**Case 24c.**—The patient was a woman aged 39. She had a large ulcer high up on the posterior wall of the stomach behind the pancreas, causing hour-glass contraction. Partial gastrectomy was done and gastro-enterostomy, but there was much infiltrated tissue left behind. Section showed it to be a typical spheroidal-celled cancer. She was given 0.585 gram of lead. This patient has done well; she has gained weight and her appetite is good. There is no sign of malignant disease.

**Case 51.**—The patient was a woman, aged 44, who, two and a half years previously, had had a radical operation on the left breast for carcinoma. On admission the abdomen was very distended and a mass could be felt in the pelvis. At the operation malignant ovarian tumours on both sides were removed. There were malignant nodules in the neighbourhood of the caecum and in the omentum, which were not removed. She was subsequently given 0.765 gram of lead. This was over two years ago; she is still quite well and has gained considerably in weight. There is no sign of recurrence.

These results lend substantial support to our views of the nature of malignant neoplasia, but much remains to be done in regard to the discovery of a more therapeutically active preparation with less toxicity. Lead is undoubtedly of value in the treatment of malignant disease, either alone or in conjunction with other methods, but we feel not only that something better may be found in the near future, but that our preparation is imperfect.

## SOME OF THE VIEWS AND WORK OF THE LIVERPOOL CANCER RESEARCH ORGANIZATION.

(With Special Plate.)

BY

W. BLAIR BELL, B.S., M.D., Hon. F.A.C.S.,

Professor of Gynaecology and Obstetrics in the University;  
Gynaecological and Obstetrical Surgeon, Liverpool Royal  
Infirmary; and Director, Liverpool Cancer Research  
Organization.

To present a composite picture of the work of the Liverpool Cancer Research Organization is difficult of accomplishment in a short space of time; but I am desirous of co-ordinating, if I can, the essential points in the investigations that have been presented by my colleagues. It is necessary, also, that I should endeavour to be so lucid that none can fail to understand. It has been a source of regret to all of us that so many friends, as well as critics, have failed to read, or, if they have read, to appreciate the outstanding simplicity of our argument, and the nature of the confirmatory evidence obtained. Moreover, in spite of repeated contradictions and demonstrations, it seems almost impossible to eradicate the prevailing idea that the use of lead by us in the treatment of cancer is based on other suggestions that have been made in regard to the treatment of malignant disease with metallic ions. I have not time to go into the early history of my own work on the subject, but this alone would refute such a suggestion, for there is documentary evidence to show that it is now about twenty years since I elaborated the views I hold to-day.

It must also be understood that anything that has a poisonous effect on normal cells may have a similar effect on cancer cells. This is well seen in the action of other metals, and of such non-metals as selenium and tellurium. The inclusion among the metals of the last two elements by those whose chemical knowledge is misled as to their character by the termination "-ium" demonstrates the absurdity of the point of view to which I have taken exception.

It is the additional specific choriotropic action of lead that gives to this element its special value.

It will, however, be my aim to impress upon you the fact

that the use of lead, however successful, may be of comparative importance only at the present time, for we ourselves chiefly esteem its action as confirmatory of other evidence bearing out the correctness of our views.

#### THEORY.

Satisfied that the chorionic epithelium—the trophoblast—and especially the outer layer of syncytium, is normally malignant in character, in that it has the powers of eroding the blood vessels and other maternal tissues in the search for nutriment, of cellular multiplication and of forming metastases, evidence has been sought to support or negative the view that the cancer cell is a reversion on the part of the somatic cell to the chorionic epithelium—that is to say, dedifferentiation occurs because the process is reversionary.

No pathologist or cytologist to-day would deny that dedifferentiation in malignant neoplasia does occur; but the reason for this cannot be seen under the highest power of the microscope, and, therefore, it has hitherto received little consideration. The so-called undifferentiated character of the cells in malignant neoplasms has been noted in general; and in respect of the cultivation of somatic tissues dedifferentiation has long been described and regarded as a malignant development. But no explanation of this has been put forward, although Champy—one of the earliest workers in the field of tissue culture—associated dedifferentiation with reproductive activity—that is, multiplication of cells.

It would appear, then, that of recent years dedifferentiation and cellular multiplication have been regarded as factors associated with malignant development; but the chief feature on which I based my original argument is that the dedifferentiation is purposeful, in that the somatic cell is returning to the normally malignant ancestral type, and that metabolic disturbances force upon it this adaptation.

I have called attention elsewhere to the fact that the only malignant neoplasm in which dedifferentiation does not and cannot occur is chorion-epithelioma. We may therefore assert (1) that the chorionic epithelium is normally malignant; (2) that somatic cells when they become malignant have reverted to, or towards, this type.

Now, if this be so, we shall expect to find supporting evidence in the following directions:

- (1) The morphological characters of the chorionic epithelium will resemble those of cancer cells.
- (2) The essential chemical constitution of the two will be similar.
- (3) The physico-chemical state will be the same.
- (4) The discriminating functional activities between the cancer cells and the resting somatic cells will be represented also in the distinction between the somatic cells and those of the chorionic epithelium.
- (5) Resemblance in the above respects will entail similarity in the toxicological affinities of the chorionic epithelium and of the cancer cell.

With regard to the first point, it is easily to be observed that the more malignant a neoplasm is, the more syncytial is the arrangement of the cancer cells (Figs. 1 to 4).

Professor Lewis has discussed the chemical constitution of the different types of cells—namely, the resting somatic, that of benign neoplasms, the malignant cell and the chorionic epithelium.

Permeability, which is such an essential requisite of growth and multiplication, is dependent on the character of the emulsion of which the cell membrane is composed. An oil-in-water type of emulsion, like milk, is clearly more permeable than a water-in-oil, like butter, for solubility in water, rather than in oil, is usual in respect of simpler food-

stuffs (see diagram). Moreover, this constitution of malignant cells explains the findings of Crile and others that the electrical conductivity of the cancer cell—through the continuous water phase—is usually greater than that of resting somatic cells. The question of alterations in the electrical capacity of the cell—found to be an increase by Crile and Fricke in the case of the cancer cell—appears to be a very difficult one, and, in the present state of our knowledge, cannot accurately be interpreted.

Now, as to the function of the various types of cells, Professor Lewis and his associates are also working along the lines of Warburg's striking investigations. Warburg has demonstrated that the power of glycolysis instead of respiration (oxidation processes) as a means of obtaining energy constitutes an essential functional difference between the

cancerous and the resting cell; that is to say, the normal resting somatic cell has practically no glycolytic power, but a high respiratory function. The cancer cell has little respiratory function, but a high selective glycolytic function in the presence of oxygen, and a very considerable glycolytic power in the absence of oxygen.

Now the chorionic epithelium, as shown by Warburg, by Murphy

of the Rockefeller Institute, and by Professor Lewis and his associates, has a moderately high respiratory function, and in the presence of oxygen shows considerable glycolytic activity—not so great as in the case of cancer. In the absence of oxygen the chorionic epithelium has the highest glycolytic power of any, not excluding malignant, tissue. In the accompanying table a rough estimate of these activities is shown.

Glucolytic Power of Normal Resting Tissues and of Innocent and Malignant Tissues.

|                                   | Respiration. | Anaerobic Glucolysis. | Aerobic Glucolysis. | Ratio Aerobic Glucolysis-Respiration. |
|-----------------------------------|--------------|-----------------------|---------------------|---------------------------------------|
| Normal resting tissues ...        | ++           | +                     | —                   | —                                     |

\* Papillomata of ... (Warburg.)

† The type of ... to that of frank malignant tissue." (Murphy ...)

Now, it may be asked why is it that the chorionic cell has not exactly the same glucolytic selective power in the presence of oxygen as the cancer cell, for it has been demonstrated that under anaerobic conditions the chorionic epithelium is the most powerfully glucolytic of any tissue. (I exclude the curious and possibly fallacious results obtained in regard to the retina.)

Warburg has shown, although the importance of the observation does not appear to have been fully realized, that if somatic resting tissues—which, in both aerobic and anaerobic conditions have practically no glucolytic power—he first starved of oxygen for a considerable time, they take on a glucolytic action after the manner of the cancer cell, though, of course, much less pronounced. Here, then, we have a clear suggestion of the metabolic disturbance which may induce the change from normal to malignant tissue—namely, oxygen starvation.

The chorionic epithelium is singularly situated: it is only in its early life that it is really malignant, and that is before a suitable blood supply with oxygen abundance has been established. It seems probable that at first all the

Diagram to illustrate the oil-in-water type of emulsion (A) favoured by a high lecithin-cholesterol ratio and permeable to water-soluble substances, typical of chorionic epithelium and the cancer cell; and the water-in-oil emulsion (B) favoured by a low lecithin-cholesterol ratio, which is impermeable.

satisfactory, but must be used fresh, as we have pointed out on many occasions.

There is still a considerable danger that if lead be used indiscriminately in the treatment of malignant disease many fatalities will follow, and the method itself, either from excessive caution or too much zeal, will be brought into disrepute. As we have already demonstrated, we ourselves have had disasters, and although our extensive experience has enabled us to avoid many more similar disasters, it is still quite possible for a patient to lose his life if incomplete investigations be carried out. Any person suffering with the slightest degree of renal impairment, or cardiac instability or disease, may die most unexpectedly as the result of a single dose. It is therefore incumbent upon us to protect the public as best we can, and at the same time to safeguard the reputation of our work. This we feel can best be done by placing the therapeutic agent, when it is available, in the hands only of those who have had some experience of the method and have ample facilities for biochemical and other investigations. This means that if there be a desire in any special clinic to try out the method, a biochemist and clinician should be sent to Liverpool to study, for, say, a week, the methods adopted, especially in regard to the selection of cases and their preparatory examination. Subsequently the experience of such men will be available for the whole clinic to which they are attached, but on them personally should rest the responsibility for the treatment and its results. "Choriotope," as we have called the preparation used by us, can only be bought with our permission, and this will not be unreasonably withheld.

At present centres have been formed in Harrogate, under the supervision of Mr. Frankling and Dr. Edgecombe, with the expert laboratory assistance of Dr. Miller. Dr. Spriggs and his associates at Ruthin Castle are fully informed of the whole procedure, and have practised it. Material made in Professor Lewis's laboratories has been supplied to these centres.

I mention these instances to give some idea of the way in which we think the method ought to be tried. We have no hesitation in saying that until the treatment has become more standardized and less dangerous, it is neither fair to the general practitioner nor to his patient that it be distributed broadcast. No doubt this statement will give rise to a considerable portion of the discussion that will take place. If this be so, we hope that it will be far removed from a personal question.

We shall, of course, be only too glad to consider any alternative or equivalent suggestions that may be put forward, for the problem is an extremely difficult one, in connexion with which we are only anxious to do what is right. At present the responsibility rests with us.

#### DISCUSSION.

Dr. SINCLAIR MILLER (Honorary Pathologist, Royal Bath Hospital and Harrogate Infirmary) said:

By the courtesy of Professor Blair Bell and other members of the Liverpool Cancer Research Committee, a small group in Harrogate has been given facilities for visiting Professor Blair Bell's clinic in Liverpool and of studying his methods. He has given us many opportunities of becoming familiar with the work he is doing, as well as much advice in the handling of our patients.

Our series consists of eighteen cases—namely:

|   |   |
|---|---|
| Recurrence after operation for carcinoma of breast  | 4 |
| Carcinoma of rectum (inoperable) ...  | 3 |
| Carcinoma of oesophagus (inoperable) ...  | 2 |
| Carcinoma of stomach (inoperable) ...   | 2 |
| Prophylaxis after removal of breast ...   | 3 |
| One each of the following: Epithelioma of groin, breast (inoperable), ovary, and gall bladder ... | 4 |

So far we have avoided any serious reactions due to the lead injections. In one case there was persistent vomiting for about ten days, which eventually subsided. In another

there was marked haematuria on the day following the first injection of lead, but as this cleared up on the second day and as there was at no time even partial suppression of urine, I think that this must have been an "accidental" haemorrhage somewhere in the urinary tract. A further injection of lead was given to this patient ten days later without any recurrence of haemorrhage. With these two exceptions, none of the cases has given us any anxiety, and on the whole there has been improvement rather than deterioration.

In most of the cases we have found it sufficient to limit the laboratory investigations to a complete cytological examination of the blood and the estimation of renal function. If the total urinary output over twenty-four hours is satisfactory and the chemical examination shows no abnormality we do not consider further renal tests necessary.

We have usually begun treatment by giving 20 c.cm. of the colloid lead in cases where there is a large amount of malignant tissue present, and 15 c.cm. in other cases where most of the growth has been removed. We repeat the dose in a week or ten days' time, unless there is some contraindication. In all cases under treatment the urinary output over the twenty-four hours is recorded and specimens are examined on two consecutive days following the injections. Prior to the next injection the blood and urine are again examined.

The haemoglobin percentage and the number of red cells per cubic millimetre are of prime importance. If the haemoglobin is much below 50 per cent. patients are given a blood transfusion, which is repeated if necessary.

Generally, after the second injection of lead and sometimes even after the first injection, the red cells show stippling or granular basophilic staining. This stippling is of importance as a guide to further dosage. In our cytological examination of the blood, we enumerate the granular basophil red cells per million red cells. If the granular basophil count rises much above 5,000 per million red cells, we delay the next injection or reduce the dose.

An interesting point that we have noticed is the appearance of a blue line on teeth affected with pyorrhoea soon after injections of lead. This has been particularly noticeable in two cases where the patients had a few teeth affected with pyorrhoea in otherwise perfectly healthy mouths; in both cases the diseased teeth showed the blue line soon after the first injection. Though the patients have had further injections of lead, the sound teeth still show no evidence of a "blue line" forming; one of the patients has had 0.475 gram of lead.

Mr. FRANK COKE (London) congratulated Professor Blair Bell on the theory which he originally evolved with regard to the similarity between the cells of the chorion and those of new growths. Each new fact since discovered with regard to the biochemical or other reactions of these two kinds of cells had strengthened his theory. From a practical point of view he was filled with even greater admiration for the way in which he brought the corollary of this theory to the practical test. Mr. Coke had been using lead for a long time with Dr. Cook of the West Middlesex Hospital, and, though not particularly nervous, yet they took two years, gradually increasing the doses of lead, to reach the large dose given by Professor Blair Bell to his first case. Most investigators would have given up the theory long before they had ever reached the large dosage necessary to kill the cancer cells. It was very fortunate that Professor Blair Bell had cured his first case, and they must not forget the pertinacity and boldness he had shown.

Mr. Coke then described his experience as a visitor to the Cancer Research Organization, where the theory of the treatment and the staff arrangements were explained in detail, and the manufacture of the lead colloid was shown. Later they saw a variety of patients in various stages of treatment, and finally a great number in whom the treatment had finished some months or years previously, the latter appearing to him to be completely cured, although Professor Blair Bell did not use that term. They were shown a young man who had had a large sarcoma invading the left scapula; a photograph of his original condition showed also a mass of glands in the axilla. When they saw

him he was entirely free from any visible growth of any kind and had been back at work for over a year. Another case was the first case treated—the woman with cancer in a lactating breast. With all these cases there were photographs of sections of the growths shown on the screen, and the actual slides were present in the room for any who cared to examine them more fully. Throughout the whole day Mr. Coke was immensely impressed by the entirely scientific basis on which the whole work was being carried out. Most of them came away, he thought, feeling that Professor Blair Bell had persistently understated his case; the benefit of the doubt was always given against claiming a cure rather than for it. Three weeks ago he spent another three days in Liverpool, when he was again shown some fifty cases in course of treatment.

While Dr. Cook and he had obtained a few striking results with the "lead M.A.," it was possible that the lead was too carefully protected in that compound. There was also mercury in it, which might or might not be an advantage. At any rate he was now using the metallic lead of Professor Blair Bell, and probably this would hold the field for the present. Fault had been found with Professor Blair Bell for not broadcasting all his work earlier, but Mr. Coke knew the months and months required to test any change in the experimental programme and to try variations in the colloids used. This treatment did not by any means cure every case, and a great amount of experimental work lay ahead; he hoped that all those who used these colloids would be willing to work with others in their neighbourhood, forming local centres which again could be in touch with Liverpool. They were endeavouring to do this in London, working on standard lines and pooling their experiences. As the committee grew they would get the team work perfected, and a demand for research was bound to follow. There need be no overlapping, and each could have the help of all. Such a combined effort in London and throughout England could at once claim public sympathy and support. What a dozen men working singly would take years to complete could be done by a team in a fraction of the time. They could thus hope to have in the near future a centre working in exactly the same way as that at Liverpool.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### A LOCAL ANAESTHETIC FOR THE EAR.

I HAVE no experience of the local anaesthetic for aural work mentioned in Dr. Pearce Sturm's note (BRITISH MEDICAL JOURNAL, October 9th, p. 638), but I have used with success a mixture advised by Dr. Caesar Hirsch, chief aurist and laryngologist to the Marienhospital, Stuttgart, and described by him in his *Lehrbuch der Lokalanästhesie des Ohres*. It consists of cocaine 5 parts, potassium sulphate (2 per cent. sol.) 20 parts, adrenaline (1 in 1,000) 10 parts, carbolic acid solution (1 2 per cent.) to 100 parts. A small mop of cotton-wool soaked in the mixture and applied to the part for five to ten minutes produces complete anaesthesia; it is even more effective than a 10 to 20 per cent. solution of cocaine. It is free from the disadvantages of setting up such complications as otitis externa, which the mixture referred to by Dr. Pearce Sturm appears to do. It is equally effective when complete anaesthesia of any mucous membrane is required—as, for example, in resection of the nasal septum.

Potassium sulphate appears to be the most efficient adjuvant in intensifying the action of cocaine (this was told me some time ago by Dr. A. R. Friel in connexion with certain methods of zinc ionization in chronic otitis media). Aniline oil also has a very marked effect in intensifying cocaine action, but is not without risk when used over a large area. For perfect anaesthesia of the larynx Dr. Hirsch recommends a 5 per cent. solution of tutocain with adrenaline and phenol. This also I have found satisfactory.

Liverpool.

#### DOUBLE UTERUS: PREGNANCY IN EACH CORNU ENDING IN ABORTION.

I WAS recently called to see a multipara, aged 35, on account of vaginal haemorrhage. Her last period was three months before, and she thought she was pregnant. She had been losing moderately for two days, and had passed "clots, but nothing else."

The patient was having intermittent slight colicky pains across the lower part of the abdomen, had not vomited, and her pulse and general condition were good. Her three previous labours had been prolonged, but otherwise uneventful, and she had never had twins or a miscarriage. The uterus was found to be enlarged to the size of a three months' pregnancy, and intermittent uterine contractions could be felt. The cervix, which was softened, would just admit the tip of the index finger. There was a small clot in the vagina, but bleeding had stopped. Nothing else abnormal was found. The woman was put to bed with the feet raised, and was given an opium mixture.

The next day, there having been further considerable haemorrhage without any sign of the uterus emptying itself, it became necessary to clear it out. The patient, who was now pale and whose pulse rate was going up, was anaesthetized with ethyl chloride and ether. The cervix now easily admitted one finger, which discovered the following state of affairs: In the main body of the uterus was a partially separated placental mass, together with a long pedunculated polypus. On exploring the left wall of the uterus about half an inch above the level of the cervix, the finger discovered a second cavity communicating with the main one by a foramen that admitted the examining finger easily. This cavity also contained a complete and separate placental mass. The relations of the accessory horn to the main body of the uterus could, when the patient was anaesthetized, be easily made out with the abdominal examining hand, and were almost exactly those portrayed on page 135 (diagram 65) of Eden and Holland's *Manual of Midwifery* (sixth edition), except that the accessory horn in my case was not rudimentary, but was functioning and communicating with the cavity of the uterus. Both cavities were cleared of their contents and douched, the polypus being twisted off at its base with vulsellum forceps. Convalescence was uneventful.

The fact that the accessory horn was functioning is of interest; as is the possible part played by the polypus in the production of uterine contractions.

#### MALDEVELOPMENT OF THE OESOPHAGUS.

I WAS much interested in the case of oesophageal maldevelopment reported in the BRITISH MEDICAL JOURNAL of April 10th (p. 652). I had a similar case in hospital practice in December, 1925, and I should be glad to know if there are any statistics as to the frequency of this phenomenon.

A married woman, aged 21, was admitted to the Matilda Hospital, Hong-Kong, on the morning of December 7th, 1925. She was in labour, and at 9.15 p.m. the same day a male child, weighing 6½ lb., was born alive. There was an excessive amount of amniotic fluid of dark green colour. The placenta was small and was easily delivered. The mother made a normal recovery.

On the second day my attention was called to the quantity of frothy fluid which the child was bringing up, and to the peculiar noise he made when attempting to take the breast. A spoonful of milk was given, and within half a minute this was returned in a frothy condition through the mouth and nose.

Suspecting some obstruction or malformation, I asked Dr. J. L. Shellshear, professor of anatomy at Hong-Kong University, to see the child with me. We tried to pass a fine rubber catheter into the stomach, but this was impossible, and under x rays the end of the catheter was seen to be coiled up in the oesophagus at the level of the fourth dorsal vertebra. A teaspoonful of bismuth and milk was given, and a skiagram showed a dark mass in the same situation. On December 13th, six days after birth, the child weighed 5 lb.; he died on December 15th at 4 p.m.

Professor Shellshear made a *post-mortem* examination and found complete atresia of the oesophagus. The upper part of the gullet ended in a bulbous dilatation, and the lower part was represented by an attenuated strand of fibrous tissue passing down to the stomach. There was no connexion between the trachea and the oesophagus. The stomach was dilated and empty. The arteries springing from the arch of the aorta were abnormal in origin. A single trunk gave rise to two common carotid arteries, and an abnormal subclavian on the right side passed posteriorly to the oesophagus at the level of the atresia.

I have stated the facts of the case without comment as Professors Shellshear and Anderson propose to read notes on it at the Medical Conference in Peking.

Matilda Hospital, Hong-Kong.

J. HERBERT SANDERS.

## Reports of Societies.

### BIOLOGICAL STANDARDIZATION OF REMEDIES.

A DISCUSSION on "The biological standardization of remedies" took place at a meeting of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine on November 9th.

Dr. H. H. DALE confined himself, in some opening remarks, to laying down certain general principles, some of which in the past, he said, had been left out of sight. Everyone would agree as to the desirability of having the activity of every remedy which was potent in therapeutics indicated in some clear and intelligent notation. There was a large and rapidly growing class of important remedies to which chemical standards for one reason or another were not applicable, and in these the necessity for biological measurement had never been called in question. No one had suggested, for example, that diphtheria antitoxin should be measured simply by the quantity injected; insulin was in the same position. There had been, however, a tendency in some quarters to doubt the need for and even the value of a biological test in the case of remedies such as digitalis and its allies, which had behind them a long history of more or less successful application in therapeutics before biological methods of assay were available, and it was urged that as digitalis differed in its action with different individuals the value of a biological standard was impaired. That point of view was not likely to appeal to the experimental worker, who held that the thing to keep in view was the absolute necessity of being able to isolate one variable factor for observation while the others were maintained as rigidly constant as possible. When a remedy had a definite and specific action which could not be accurately gauged by chemical tests, but could be measured by a biological test, this latter ought always to be made. Another obvious principle was that the word "standardization" had no proper use except in relation to some generally accepted standard. Hitherto progressive manufacturers who recognized the need of controlling the activity of certain remedies by biological tests had had no official standard to work to. They had accordingly worked to standards of their own—no blame was imputed to the manufacturers—and the result had been to strengthen the resistance of conservatism and scepticism with regard to the desirability of general standardization. Already, however, the standards for diphtheria and tetanus antitoxins, insulin, and salvarsan, to mention no others, had been defined by international agreement at conferences attended by representatives of as many as nine nationalities meeting under the auspices of the Health Committee of the League of Nations, and much useful work had been done in that direction, and was continuing. Dr. Dale went on to urge that the proper basis of all biological standardization must be comparative. To lay down biological tests in absolute terms of some animal reaction was bound to lead to confusion—a point which he exemplified by the confusion which was threatened in the case of insulin when people in different countries tried to define its activity in terms of different animal reactions. The Edinburgh conference in 1923 declared that the activity of insulin ought to be evaluated by comparison with a stable standard, and this had now been prepared and was kept at the Institute at Hampstead. With regard to the methods of biological comparison, it might seem almost superfluous to demand that they should be reasonably accurate in measurement, and that what was measured should be the therapeutic activity of the substance under test; but experience had shown that it was really necessary to insist upon so elementary a point as that.

Dr. J. W. TREVAN gave details of certain well established tests for remedies not standardizable by chemical methods. The errors which came in were largely—almost entirely—due to the variability of the animal or isolated organ which was used for the test. He indicated the difficulty by describing an experiment in which 250 frogs had been injected with strophanthus, and it took three times as much per animal to kill all the frogs as it took to kill

a very small proportion of them. Similar variations took place with the isolated organs. The variations as between one frog's heart and another were of the range of 1 to 200. The first method of eliminating this factor of variability was to use some reaction of the animal or the isolated organ which was quickly reversible so that the test could be repeated within a comparatively short time. Not all drugs could be so tested, but the method had been used with adrenaline and pituitary extract and with some preparations of digitalis. If the action was not reversible the conditions of experiment were much more difficult. In that case the way to eliminate the errors due to variability was by using large numbers of mice or of frogs, as the case might be, so increasing the number of tests, and working out the values for the proportion that died. This applied to the testing of digitalis on frogs and on cats and the testing of insulin on mice. Not only did one animal differ from another in sensitivity, but the whole stock of animals showed periodical changes. The average lethal dose for insulin and digitalis and for a number of other drugs—though not for all—might vary. Until it had been demonstrated that any given lethal dose method did not suffer from the shift in the average lethal dose it must always be assumed that such a shift might take place. There was another way in which the disadvantage of non-reversibility in the action of a drug might be overcome—namely, the method of injecting digitalis tincture into the vein of an anaesthetized cat until the heart just stopped, and finding out the dose necessary to produce that effect. The statistical error in that method was rather less than in the method of injecting a large number of animals and working out the figures from the percentage of mortality.

Dr. J. H. BURN drew attention to the close relations which had now been determined between the results of laboratory and clinical methods in many instances. In a comparison which had been carried out between the laboratory method of testing insulin and the clinical method the agreement was extremely good. Certain laboratory tests with rabbits carried out at Hampstead by Dr. H. P. MARKS had been compared with certain clinical tests done by Drs. Lawrence and Harrison, and the results made it clear that the laboratory was measuring what the clinician wanted. The same was true with regard to digitalis. There had been one or two previous attempts to show that the variations in the testing of digitalis by the laboratory method were significant for the clinician, and such efforts had not always been successful; but certain figures which he showed, obtained in Baltimore, indicated that the effect of various preparations of digitalis on the cat and on the patient followed the same order. The workers in Baltimore, in their clinical observations, instead of using small doses maintained over a series of days, gave one single large dose and determined the effect. All the cases were of auricular fibrillation which had not had digitalis for some long time. While there was no close identification between the two sets of figures, there was a general measure of agreement, and that, in the case of an agent given by the mouth, was, he thought, all that could be expected. It was important that clinicians should realize that pharmacologists did work on the understanding that what they were measuring in the laboratory was what the clinician wanted.

Dr. GEORGE GRAHAM (from the chair) said that he did not think clinicians had any idea of the amount of work done for their service in the laboratory. He agreed that the fact that patients exhibited idiosyncrasies to digitalis was no ground for objecting to the standardization of the drug. There were no means of calculating for these idiosyncrasies, but he thought the original introducer of digitalis into medicine would be heartily with Dr. Dale in insisting on its standardization.

Dr. DALE, in reply to a remark of Dr. Trevan's on the difficulty of standardizing vitamin value, said that he thought the compilers of the United States Pharmacopoeia had been precipitate in introducing a test supposedly for the vitamin A activity of cod-liver oil, in view of the fact that the whole vitamin question was in a state of flux. If anything was going to be done along that line, the only sound principle would be to establish in this case also a stable standard by which workers in different

countries could standardize their animals, otherwise there would be nothing like real consistency. Mere consistency on paper which did not correspond to realities was worse than an acknowledged confusion.

### THE BIOLOGY OF HYDATID INFECTION.

A MEETING of the Section of Tropical Diseases and Parasitology of the Royal Society of Medicine was held at the society's rooms on November 3rd, with Dr. J. B. CHRISTOPHERSON in the chair.

Dr. T. W. M. CAMERON, discussing some modern biological conceptions of hydatid disease, said that in the past it had generally been considered that only one species of echinococcus—the adult parasite of the hydatid intermediate stage—existed, but Deising had described a second species from a puma. The speaker had found the same form in another species of South American cat, and also two other forms which he considered were new species—one from the wolf in Macedonia and the other from the Cape hunting dog. He believed that further species would probably be discovered. The development of hydatid had recently been studied in great detail by Dévé and Dew, and this was illustrated by drawings shown on the epididymoscope. The normal hydatid only contained brood capsules and scolices. Daughter cysts were abnormal, and only occurred as a reaction against something which threatened the continued existence of the parasite. Daughter cysts were common in human beings between the ages of 20 and 40 when the parasite was relatively old. The majority of infections occurred in young people, and in them daughter cysts were seldom found. Endogenous daughter cysts developed from fragments of germinal membrane, from brood capsules, or from isolated scolices. In the past exogenous daughter cysts had been believed to arise by inclusions of germinal layer in the cuticle of the parasite. These inclusions were gradually passed to the exterior of the hydatid by exfoliations of the cuticular layer, when they became vacuolated and formed cysts. Dew, however, believed that these cysts, limited practically to omental and osseous hydatid, were caused by herniations of both layers of the cyst through the adventitious wall. The necks were subsequently constricted off, and the cysts became more or less free from the mother. Granddaughter cysts could also be formed in the same way. The different types of hydatid in the various domestic animals and in man were then considered. The sheep was the optimum host, and in it the cyst was simple, and generally spherical, although multilocular forms were occasionally encountered. These were merely modifications of the simple cyst, caused by the sclerotic reaction of the host organ. The typical form in the ox was usually a sterile, encapsulated, multilocular cyst, which was surrounded by a peculiar trizonal arrangement of cells—an inner layer of columnar cells, a middle layer of round cells, and an outer layer of concentrically arranged connective tissue cells. In the pig and the horse the common form was a simple cyst, or one with a slight degree of saccululation. In man, in certain isolated regions, there was found a peculiarly malignant form called alveolar hydatid, which consisted of a network of small irregular cavities lying in a necrotic amorphous stroma. The development of this form was characterized by a double process—a peripheral infiltration of the liver (or other organ) by the parasitic elements, and a progressive excavation of the parasitized mass, often resulting in the production of a large central cavity filled with a sero-purulent fluid. It differed from the bovine multilocular form essentially in showing no tendency to become encapsulated, and by its infiltrations and metastases, resembling a malignant neoplasm. It could be accounted for by a dissociation of the functions of the germinal layer (as had been suggested by Dévé)—for example, the germinal layer did not lay down cuticle as fast as it grew, which the normal cyst did, and so the naked protoplasm came into contact with the host substance and poisoned it. Dew considered that the study of the normal life-history, with its three successive stages, could explain the existence of the various forms found. The active newly implanted embryo caused toxic and inflammatory changes in the tissue; if, for some reason not yet known, this was exaggerated a typical alveolar picture would result. In the second stage there was an active cellular reaction by the host and a trizonal arrangement of the cells; if this stage persisted the bovine multilocular form was seen. The final stage was an accurate balance between parasite and host with the production of the typical hydatid. While there was little doubt that more than one species of echinococcus existed, there was no reason to suppose that the different forms were necessarily due to different species. That the alveolar variety was caused by a separate species had for long been the common opinion, but the discovery of isolated cases outside of the endemic areas militated against this hypothesis, and the fact that it was found only in man made its continued existence impossible. It had been suggested that the bovine form might represent the same parasite in another host (although the geographical distribution did not coincide), but the histology was opposed to this view, and, moreover, this form was invariably sterile. The trend of modern opinion was that all the forms were different manifestations of the same species, the variations being due to histological peculiarities or hypersusceptibilities of the hosts.

Dr. ALDO CASTELLANI read a paper on some aspects of chronic colitis, in which he discussed the classification and characteristics of the various organisms concerned. Illustrative examples of cases which he had treated were quoted.

Dr. R. J. ORTLEPP discussed the various species of the genus *Physaloptera* in man. Two human species of this roundworm had usually been considered to exist. A recent examination by Schulz of the type material of the older of these two species had shown that its original description was very poor; so far from being distinct from the other species, it was obviously very closely related to it. An examination of the type material of the second species by the speaker showed that no differences of a valid character could be found, and he was impelled to conclude that the name of the second species, *P. mordens*, must be suppressed in favour of the older *Physaloptera caucasica*; only one species was found in man.

Dr. S. ANNECKE read a paper on the number of male and female gametocytes in human malaria and in *haemoproteus* in birds. One important factor, he said, influencing the infection of the mosquito—whether under natural or experimental conditions—carrying human malaria was possibly the relative proportion of male and female gametocytes present in the peripheral circulation at the actual time of feeding. Most of the literature dealt only with subtertian malaria and contained little information regarding the other two species of human malaria. The most reliable counts obtained by previous workers in subtertian malaria indicated that there were about three times the number of female as of male gametocytes present. From his own cases, Dr. Annecke found that the ratio of female to male gametocytes in *P. falciparum* and in *P. vivax* was about 3:1; in *P. malariae* it was 4:1; while in *Haemoproteus* it varied from 1:1 to 1:1.5. From a detailed examination of his data he desired to emphasize two facts: the incidence of gametocytes in the peripheral blood at certain periods of the disease varied from day to day, and the percentage of the sexes also varied. That might result from an attempt to establish a correct balance in the numbers of the male and female elements circulating in the peripheral blood in order to give the most favourable chances for fertilization, and so for the propagation of the species. The proportion of sexes varied for the different species as had been noted above. In human malaria it was only when the right proportion of male and female gametocytes circulating in the peripheral blood was obtained that the most favourable conditions were present for the parasite to complete its life cycle.

Dr. P. MANSON-BAHR pointed out that the preponderance of female over male was not confined to the sporozoon parasites. Fairley had recently shown that female schistosomes were more especially affected by the parasitocides, and he thought that an investigation into this question in connexion with malaria would be fruitful. He had been much puzzled by the action of the new antimalarial drug plasmoquine on the gametocytes of malaria. It was possible that this could be explained by the rapid action of the drug on the young trophozoites, which would cause an apparent rapid destruction of the gametocytes.

# THE MANAGEMENT OF INFECTIONS IN BOARDING SCHOOLS.

A DISCUSSION took place at a meeting of the Medical Officers of Schools Association on November 12th, Dr. L. R. LEMPRIERE presiding, on possible modifications of the rules hitherto observed in the management of infectious diseases in boarding schools.

Dr. A. I. SIMEY (Rugby School) said that from the point of view of keeping schools free from infection, he did not think that the usually accepted rules of quarantine for those who had been exposed to infection during the holidays could be made less stringent, and indeed the rules might well be extended to cover the common catarrhal infections. Chicken-pox was now so mild that he thought it might be removed from the list of scheduled infections in boarding school regulations. He would also be prepared to remove rubella were it not that there was often considerable difficulty in distinguishing this condition from measles. With regard to the hospital beds to be provided for boarding schools, it would be unreasonable to expect accommodation in the school hospital for all cases of illness in big epidemics; this would mean making provision for 40 per cent. of the school population. But he thought the minimum percentage of beds to be recommended should be between 10 and 20 per cent., a certain number of these to be assigned for surgical and non-infectious cases. With regard to the treatment and prevention of spread when once infectious disease had manifested itself, the wards should be arranged so that, when two or more separate infections occurred simultaneously in the school, the cases in each category could be kept apart the one from the other, and also from non-infectious cases. During convalescence patients should be allowed one or two daily walks and at least one bath a day. Among disinfecting measures he considered that fumigation by formalin vapour, at least in such concentration as was usually adopted, did little or nothing more than give a sanitary smell and a false feeling of security. Fresh air, sunshine, and soap and water were the best disinfectants. In mild uncomplicated affections the boy was safely discharged when clinically fit to return to school. In the case of scarlet fever a minimum of six weeks' isolation was desirable, though a few cases were fit to be discharged at the end of four weeks, the difficulty being, however, to say which cases these were. A few cases continued to have a residual infection, located, he believed, in the naso-pharynx, and possibly flaring up again if the convalescent developed a cold. The naso-pharynx in all these conditions was what really mattered. In the case of measles a boy was never fit to return to school until after at least fourteen days from the full development of the rash. Patients suffering from chicken-pox were nearly always detained too long. He saw no reason to alter the rules with regard to mumps and whooping-cough, though the actual period of infectivity was probably short. With regard to washing, he thought that the underclothes in infectious cases should be washed either at the sanatorium laundry or else sent to a special laundry. They should not be sent to the ordinary school laundry or to a laundry serving the general public, as infected school linen might possibly extend infection to the outside community. A great deal had still to be learned about infection, especially as to its passage from one individual to another, and school doctors had been prone to attack the infection too little in its initial stages and too much when it was gradually subsiding.

Dr. DUNCAN FORBES (M.O.H. and S.M.O., Brighton) agreed with much that Dr. Simey had said. In Brighton there was a hospital which dealt with young children suffering from surgical tuberculosis and also with those suffering from scarlet fever and diphtheria. All nurses in attendance on these cases mixed freely with each other, sometimes even sharing the same bedroom, and there had been no spread of scarlet fever or diphtheria to the tuberculous children. With regard to disinfectants, soap was probably as effective as any, and danger was at a minimum if thorough cleansing were carried out. At the sanatorium laundry, of course, care was taken that the clean linen went out at a different door from that at which the used

linen came in. Infected articles were immersed in water as soon as they reached the laundry. He did not think that special laundries were necessary for infectious cases if these precautions were taken. For the general prevention of infection in schools he was rather inclined to trust to the following by the pupils of instruction in such habits as covering the mouth when coughing, washing the hands before meals, and refraining from putting pencils or fingers in the mouth. With regard to "carriers," he was of opinion that if "carriers" were thoroughly examined some morbid lesion would almost invariably be found.

Dr. ELWIN T. NASH (M.O.H. and S.M.O., Heston and Isleworth) pointed out that in public schools it was necessary to play for safety. Much as they might wish to shorten the time of assumed infectivity, it would be rather drastic to start altering the code of rules in view of the large safety factor which was necessary in these cases where a young and growing population was massed together, not always under the best conditions. He scarcely shared Dr. Forbes's trust in the effect of hygienic discipline among boys. He had been surprised to hear Dr. Simey say that formalin disinfection was of little use. One important point was that, to be effective, it must be carried out in a moist atmosphere. Dry formalin disinfection was a poor thing to which to pin one's faith. He supported certain remarks which Dr. Forbes had made as to the lack of proof that disease was caused by drains. The nearest connexion he could trace between drains and diphtheria was that both began with "d."

Surgeon-Captain MAX, R.N., said that during the last six years at the Royal Hospital School, Greenwich, there had been only one epidemic, with 127 cases of scarlet fever and 107 of diphtheria. In the case of diphtheria the contacts were taken—the boy who had been next to the patient at meals, at desk, at games, and in the dormitory—and diligently swabbed, but very rarely was he able to say definitely that one boy had taken the disease from another by contact. During the last term there were nine cases of measles, but he was quite unable to say why the infection did not spread.

Dr. J. YOUNG (Bishop's Stortford) thought that more might be done when the first case of measles or other malady made its appearance. The first case should be rigorously dealt with and disinfectant measures taken. The dormitories appeared to him the most likely centre for the spread of the disease, and another danger-point was the scrimmage in Rugby football.

Dr. L. R. LEMPRIERE (Haileybury College) said that any changes which were made in the code of rules would have to be made very circumspectly. At the same time, the position should be examined dispassionately and critically with a view to deciding how far the rules, which had now been in vogue for many years, had stood the test of experience. The waste of time and money involved in a long quarantine had to be considered. For all practical purposes one attack of these infectious diseases conferred immunity. Second attacks were so rare that they could be disregarded. From time to time he read correspondence in the BRITISH MEDICAL JOURNAL regarding a supposed second attack of measles, but the history given was absolutely typical of rubella. At his school the boys were seen only from the ages of 13 to 18, but during that period he was perfectly certain that second cases occurred only in the rarest instances. He had seen one second case of rubella—a typical attack occurring three weeks after the first. One could never be sure whether on the appearance of a first case of varicella or mumps an epidemic would follow or not. Over and over again varicella cropped up in the middle of winter, and there were a number of single cases. With regard to sending boys home, school authorities had to play for safety, and, to guard themselves from possible action, they had to practise disinfection perhaps on a scale which they might not consider really necessary. With regard to the length of the period of infectivity, the condition of wellness of the boy, practically speaking, was the guide. A case of measles was never fit to return until after three weeks, and then only when the condition was good. The patient with varicella should be kept in for ten days, and if his clinical condition

justified it and his face was clean aesthetically he might return to school. For mumps two weeks at least must be allowed in order to avoid orchitis, which might occur later on. Catarrhal conditions needed very careful consideration and more action than was at present taken upon them. He agreed that it was the naso-pharynx which needed looking after. In the first case he would deem it worth while to practise disinfection; after that he did not think it would be of the slightest use. Cleanliness—soap and water—was the great essential. With regard to the laundry, for the last twenty-five years the practice at Haileybury had been to soak in disinfectant the clothing from an infectious case, and then send it to the ordinary school laundry, and he had never known a case in which the laundry women or their families had caught any infection.

Dr. W. G. WILLOUGHBY (M.O.H. and S.M.O., Eastbourne) described how, when he went to Eastbourne, he persuaded the headmasters and headmistresses of the many schools in that town to let the local authority build sanatorium blocks for all school cases, which could thus be concentrated in one place instead of being spread over a number of little local fever hospitals, and this plan had worked well. With regard to the carrying of an infection by third persons, he remembered, when assistant medical officer at Plymouth, that certain small-pox cases were kept on board a ship in the harbour, whereupon small-pox broke out in the town, and it was discovered that in the dark some friend of the man in charge of the ship had gone ashore wearing a coat belonging to one of the patients on the ship and had called at a house in the town. A crop of scarlet fever cases occurring in ones and twos week after week had been eventually traced to a particular place in chapel, where every one of the boys affected had sat. The place was cleaned up and the prayer books destroyed, and no further cases occurred. In another school the source of infection was proved to be a book in the library, which had been taken out successively by boys each of whom took the infection. As a rule he thought carriage by third persons very unlikely. As for drains, while he did not believe that infection arose from them, he thought it important that they should be in good condition, as a bad odour might affect the general health, and so lower the resistance to infection.

Dr. H. W. ATTLEE (Eton College) said that the code had been of use as a means of reference for school medical officers, but he thought the time had come when general principles ought to be reviewed. He was convinced that all infections were very rarely carried, with the exception of scarlet fever and diphtheria. In public schools he was afraid they were too much inclined to play for safety.

Dr. J. LAMBERT (Wellington College) thought that before the boys left at the end of the term they should be examined to make sure that they had no infection. After the occurrence of the first case it was extremely difficult to stop an epidemic. Cases cropped up in various directions where no contact could be proved. Boys mixed with one another in all sorts of ways; in some cases a chance cough as one boy passed another in the "quad" might spread infection. Unless a boy was seriously ill in school he did not think his parents should be in the least encouraged to go and visit him.

Dr. G. E. FRIEND (Christ's Hospital, Horsham) said that his experience was that of the epidemics of infectious disease occurring during the last thirteen years at his school very nearly 60 per cent. occurred in term time after the lapse of such a period as proved that the infection could not have been incurred at home. About 40 per cent. occurred after the beginning of term within the possible incubation period of an infection originating during the holidays. There was very little doubt that the other epidemics were due to the introduction of visitors.

After further discussion, in which it was suggested that tonsillitis, influenza, and "pink eye" should be added to the list of maladies specially provided for in the code, it was agreed, on the motion of Dr. ELWIN NASH, to refer to the council the possibility of forming a joint committee with the Society of Medical Officers of Health in order to go into the proposed modifications of the code of rules.

## OBSTRUCTION OF THE DUODENUM.

At a meeting of the Liverpool Medical Institution on October 28th Mr. G. C. E. SIMPSON read a paper on some obstructions of the duodenum.

Mr. Simpson said that morbid conditions of the duodenum, apart from ulcer, were a frequent cause of indigestion, and probably often an exciting cause of ulcer. He alluded to diverticula, extension of growth or inflammation from neighbouring structures, tuberculous stricture and obstruction by bands, and adhesions from tuberculosis outside it. Cases of congenital malposition were mentioned, and in one of these he had met with an appendix which "controlled" the duodeno-jejunal flexure. Nagel's case of congenital diaphragm of the duodenum was mentioned, where the patient survived to the age of 72, and a personal case was quoted where a man aged 24 had a stricture 2 in. long and 1/2 in. in diameter in place of the pylorus. Morley's classification of biliary cysts was given, and a case mentioned in a man where the cyst invaginated the wall of the duodenum from the biliary papilla to the superior mesenteric artery and there caused obstruction. The cyst contained about thirty ounces of fluid, with elements from the bile and pancreas and a few stones; a duodenal ulcer was also present. In these cases the symptoms of indigestion were chronic, but slight, for years; they then became more acute with dilatation of the stomach. Flatus was troublesome. Passing to acute arterio-mesenteric ileus—post-operative and idiopathic—Mr. Simpson quoted a fatal case of the latter condition where washouts and posture failed to give relief, and the only operation possible was jejunostomy. Chronic duodenal ileus was then considered. A well marked case in a girl aged 12, treated by a belt, and other early cases, treated by colopexy, were mentioned, and then the treatment by: duodeno-jejunostomy and by gastro-enterostomy. The last procedure had been used in cases where the symptomatology was particularly suggestive of ulcer, and where there was marked hyperchlorhydria; most of the patients were males, and the results were good. Of the fourteen duodeno-jejunostomies half were cured or with slight discomfort, two were recent, three were definitely failures. In view of the long-standing history and the other troubles, such as previous and associated operations, these results were satisfactory. All the cases showed enteroptosis, and a slide was shown recording the lower border of the stomach and the upper level of the hepatic flexure in these cases as contrasted with a similar number of cases taken at random. Mr. Simpson then passed to consideration of bands from the gall bladder and ducts to the duodenum and colon. Apart from adhesions definitely attributable to inflammation, such bands were common, and often the only lesion present in cases suggestive of duodenal ulcer or gall stones; their release was beneficial. The speaker considered that proliferative changes in reaction to strain were responsible for these, though in many cases the basis was of congenital origin. Again, most cases showed enteroptosis, of which disease he suggested Nebuchadnezzar was the first recorded victim. A case was then noted with duodenal delay and prolapse in which it would appear that the obstruction was at the duodeno-jejunal flexure, probably from the duodeno-jejunal band, but the case was still under observation. Slides were shown of very convincing radiographs by Dr. Oram. In general, obstructions of the duodenum tended to give a picture with periodicity. The pain was often relieved by food or by hot drinks. Both the intervals and the duration of the attacks were different from those of duodenal ulcer, the attacks being short. Flatulence was the other constant feature.

## Clinical Significance of Cardiac Murmurs.

Dr. T. W. WADSWORTH, in a note on cardiac murmurs, described the physical factors responsible for murmur production, and discussed the various theories held responsible for the presence of murmurs in cases in which no anatomical or pathological causes could be found. It was held that the term "accidental" should be employed when describing murmurs of this type, qualifying it by such distinctions as "haemic" and "cardio-respiratory," when the presence of these factors could be substantiated. The diagnosis of

"accidental" from "organic" murmurs was described, and also the estimation of the degree of stenosis and the functional condition of the IV bundle and auricle as deduced from the character and presence of the presystolic murmur.

## TREATMENT OF FRACTURES OF THE MANDIBLE.

At a meeting of the Aberdeen Medico-Chirurgical Society on October 28th Dr. JAMES CROMBIE delivered his presidential address on the treatment of fractures of the mandible.

Dr. Crombie said that the treatment of fractures in this situation had undergone considerable advancement during his thirty years in practice. The commonest causes of fractures of the mandible were motor-cycle accidents, blows with the fist, kicks from horses, and industrial accidents. The fracture was generally compound into the mouth, the usual position being in the bicuspid or canine region. Very often this was accompanied by a fracture of the angle or ascending ramus on the opposite side. Oblique fractures were the rule, although transverse fractures were met with occasionally at the symphysis. In addition to the usual symptoms of fracture there were several special features in fracture of the mandible—namely, a little haemorrhage into the mouth, inability to close the mouth and to articulate the words properly, and dribbling of saliva. The fragments could be seen to move when the patient swallowed, and there was usually a definite irregularity in the line of the teeth. In single fractures the smaller fragment usually overrode the larger; in double fractures the centre fragment usually dropped downwards. Dislocated teeth were very common, and care should be taken that a tooth had not dropped between the fragments. Fractures of the ascending ramus were usually accompanied by much swelling but very little displacement. Crepitus, difficulty in moving the jaw, and deviation to the affected side were the symptoms of fracture of the neck of the condyle.

The speaker then described the various methods of fixation of the fragments of the fractured mandible by bandaging, splinting, and wiring the teeth, each method being useful in suitable cases. An oblique radiograph should be taken before the treatment was commenced. Preliminary cleansing of the mouth was necessary, as well as a dose of antitetanic serum. In the region of the ascending ramus and angle very little in the way of treatment was required except the support of a bandage. Where there was displacement of the fragments of the mandible and splinting was to be used impressions of the upper and lower jaws should be taken in modelling composition. Impressions of these were cast in plaster-of-Paris, and, if the fracture was in the dentigerous area, the lower model was sawn through the site of the fracture, and articulated with the upper model, so that the condition of the jaws was the same as before the fracture occurred. Numerous types of splints had been devised for fixation, but most of them were modifications of the classical Hammond or Gunning splint, both of which were described. The original Hammond splint consisted of a piece of wire which was fitted round the inside and outside of the teeth in the lower jaw; after reduction of the fracture into this splint fixation was obtained by figure-of-eight wiring round the teeth. Iron wire had been originally used, but this, in practice, was too soft, had an unpleasant taste, and in addition stained the teeth. More recently gold, dental alloy, or German silver gilt had been employed. A modification of this had been devised by Dr. Crombie, bands being fitted round the necks of the second bicuspid, or other suitable teeth, and a band fitting the inside and outside of the intervening teeth soldered to these. The original Gunning splint was made of vulcanite; it covered both upper and lower teeth and part of the gum, with a hole in front for speech, and one at each side to allow the saliva from the parotids to enter the mouth. For cleansing purposes it was drilled all over with small holes. The fragments were reduced into the splint and the jaw was held up

by a four-tailed bandage. The modern splint was made of metal and only covered the teeth; the upper and lower cups were soldered together if the mouth was to be kept shut, and if the mouth was to be kept open they were joined by soldered struts. This splint was usually cemented on to the teeth, and an aluminium chin support was used for a day or two. The method of making these splints was described, and numerous models were exhibited to show the modifications required for various cases. Dr. Crombie thought that fractures in the dentigerous area of the mandible should be treated by a single Gunning splint, cemented on. In this way the temporo-maxillary joint did not stiffen, and after a few days ordinary food could be taken. It was possible to use this splint only when there were teeth on each side of the fracture, otherwise a double Gunning splint had to be used. He emphasized the point that shaky teeth should be left, as they often healed and became firm; if this did not occur they could easily be removed later. In cases of comminuted fracture with much sepsis a Payne's cradle splint was recommended—almost a double Hammond—the upper and lower splints being held together by cross-struts. Free drainage was thus obtained, and the mouth could be washed out easily with an antiseptic solution. The treatment of cases where there was much bone loss was described, including cup and bar splints and bone grafts. It was of the greatest importance in these cases to keep the fragments in their proper relation to the upper jaw. The method of wiring the teeth was demonstrated, and in edentulous people wiring or fixation of the bony fragments by kangaroo tendon was recommended.

In concluding his address Dr. Crombie stated that no matter how a fracture of the mandible was being treated absolute cleanliness of the mouth was essential. Syringing with a solution of liquor potassae and carbolic acid of 1 in 40 strength should be practised before and after each meal; if the splint was detachable it should be removed and boiled. The food must be soft, but with the aid of a mortar and pestle a varied menu could be given.

## JAMES MACKENZIE INSTITUTE.

In a lecture on disturbance of renal function in experimental nephritis given to the James Mackenzie Institute for Clinical Research, St. Andrews, on October 26th, Professor SHAW DUNN referred first to the object and scope of his research into experimental nephritis in animals. He pointed out the difference between the acute form of the disease as seen in the rabbit and in the human subject, and showed the essential lesion in the former to be in the first convoluted tubule, and not in the glomerulus. He made the interesting observation in this connexion, however, that albuminuria did occur, and hence it might be presumed that some functional change took place in the glomerulus also. He next proceeded to detail the results obtained in rabbits in which nephritis had been induced by a sufficient dose of oxalates, showing the diminution in urinary nitrogen excretion and the increase in the blood urea, sometimes to high levels. There was also present, he stated, acidosis, and he drew attention to the probable additional function of the renal tubule in maintaining the body's alkaline reserve. The diminution in the percentage of urea excreted and the rise in blood urea showed a diminished power of concentration on the part of the kidney. There might be produced, however, by the injection of saline an artificial polyuria which washed out the urea in large quantity and brought down the blood urea level. The lecturer then put forward the view that the urea retention might be explained by the hitherto impermeable tubule cells being killed or damaged and hence becoming permeable and permitting urea to reabsorb. So also anuria might develop. The few experiments which had been possible on chronic tubular lesions confirmed the main conclusions, and showed the importance of an adequate supply of water to secure a sufficient excretion of urea and the danger of reducing this supply in cases in which the concentrating power of the kidney was permanently lowered.

## Rebiew.

### METHODS AND PROBLEMS OF MEDICAL EDUCATION.

THE fourth series of *Methods and Problems of Medical Education*,<sup>1</sup> brought out and distributed by the Division of Medical Education of the Rockefeller Foundation, is devoted entirely to an account of the method of taking, filing, and storing the notes of patients in the Presbyterian Hospital, New York, which, after an examination by Dr. R. M. Pearce of the Rockefeller Foundation of several other admirable and more or less widely known methods, appears to be the most suitable. Dr. W. W. Palmer, physician-in-chief to the hospital and professor of medicine in Columbia University, has been active in the preparation of this instalment of the series. There are three articles; the first is short, and describes the record room, with its seven record clerks under the direction of a committee of three members of the medical and surgical staff; it is responsible to the medical board, which in its turn is responsible to the board of management of the hospital. The position of the record room is important, though little consideration has apparently been given to the point in the construction of existing hospitals; it need not be near the wards, as is so frequently the case, for when a person is admitted as an in-patient his history is kept there until he is discharged; the record room should be easily accessible to the out-patient rooms, the follow-up and social service organizations, the laboratories, the museum, and the library. The rules for recording and filing medical and surgical histories are given in the second and longest article, on the unit history system. It is by Dr. H. Auchincloss, visiting surgeon to the hospital, and contains illustrations of the history sheets, index cards, and of the letters and memoranda for patients. The methods used in the follow-up system, with reproductions of the letters sent to patients who fail to report, are also described in this article. The thorough character of the system is shown by the record that 91.6 per cent. of the patients were in some degree followed up. The methods of the surgical follow-up system are considered in a separate article by Dr. J. H. Corscaden, assistant consultant in gynaecology. Much the larger part of the pamphlet is the appendix containing facsimile reproductions of the charts and various kinds of notes taken in the hospital.

The fifth series contains no fewer than twenty-two articles describing different teaching and research departments in twelve centres of North America, China, France, and Holland. The majority of the departments described are concerned with the pre-clinical sciences, physiology being well represented by the laboratories of Washington University, St. Louis, Pennsylvania University, McGill, and the Peking Union Medical College. The pathological department of Washington University is described by Professor Leo Loeb, and that of Utrecht University by Professor R. de Josselin de Jong. The account by Dr. Béla Schick of the charting of clinical records at Mount Sinai Hospital, New York, serves as a supplement to the last series; a coloured chart of the weight, measurements, diet, and other details of a baby during nine months presents inset photographs of the patient before and after treatment—a graphic record from the children's clinic in Vienna. Dr. Ralph Pemberton, director of the medical division of the Presbyterian Hospital, Philadelphia, gives an account of the new dispensary or out-patient department, with its laboratories, post-mortem room, clinics, and research rooms. Professors E. Estor and J. L. Pech of Montpellier explain by illustrations the mechanism and use of the surgical didactic lamp, by means of which onlookers either at a distance or even outside the theatre can watch operations. A specially interesting article on the prophylaxis of mental disorder is contributed by Dr. P. Toulouse, director of the laboratory of experimental psychology attached to the Asylum of St. Anne, Paris. About seven departments at McGill University and four at Washington University are dealt with successively; closer correlation of the various

subjects has been specially aimed at, and in many instances the various allied sciences have been collected under the same roof. Writing on the Students' Unit Medical Laboratory at the University of Wisconsin, Dr. Chauncey D. Leake, associate professor of pharmacology, points out the need for intimate friendly relations and the personal touch between the teachers and the taught, and the disadvantages of departmental barriers between anatomy, physiology, pathology, surgery, and medicine. In this system four students are allotted a room where they keep their books, read, work, and do experiments. For the average medical class of 100 students satisfactory accommodation is provided by twenty-five such rooms on one floor. The provisions made for research form a prominent feature in these articles—for example, all the whole-time members of the staff in Professor A. B. Macallum's department of biochemistry at McGill University are engaged in original work, and in the physiological laboratory of the same university the stimulus exerted by the M.Sc. has been successful. The volume is profusely illustrated by photographs and plans of the laboratories; Professor Robert J. Terry's account of the departments of anatomy, neuro-anatomy, and histology at Washington University contains twenty-six such illustrations, many occupying a whole page.

The value of these publications to teachers, especially those responsible for building or reorganizing their departments, is too obvious to need elaboration.

### RADIOTHERAPY IN GENERAL MEDICINE.

DR. FRANCIS HERNAMAN-JOHNSON, in a small book entitled *Radiotherapy in Relation to General Medicine*,<sup>2</sup> has endeavoured to show, in a comparatively brief compass, the relation of this branch of therapeutics to medicine as a whole. The book is not a textbook, and contains very little on technique; it is not primarily written for the radiologist, but is meant to give a general idea of the scope and possibilities of radiotherapeutics to the non-expert. A comparatively large amount of space is allotted to the treatment of cancer and Graves's disease, and is based on the personal experience of the author; x rays are dealt with more fully than other forms of radiation.

The earlier chapters deal very simply with the physics of radiation and the effect of radiation upon normal cells. The two chapters on cancer deal with the principles of the treatment, and discuss the comparative value of radiation treatment in various forms of the disease. Many cases are quoted shortly, but in sufficient detail to show what effects are produced and what results can be obtained; other cases are related which tend to show the limitation of the treatment.

A chapter on uterine fibromata and tumours contains an excellent summary of radiation possibilities in these conditions, and again illustrative cases are quoted. He considers that during the next twenty years the use of x rays in uterine and ovarian disease will become much more general: the ease and complete safety with which sterilization can be brought about by measured doses of deeply penetrating x rays is mentioned.

The author is an enthusiast for x-ray treatment in Graves's disease and allied conditions, and states that "the patient acutely, even desperately, ill is the one in greatest need of radiotherapy"; this seems to be correct, for patients far too ill for operation may improve rapidly and immediately under the administration of x rays. There is a further chapter on tuberculosis and other disease.

This book is well written and full of interest, and the author, in a small space, has succeeded in giving a vivid picture of the great scope and importance of radiation therapy as carried out by modern methods.

### THE CARRIER PROBLEM.

As no handbook on the carriers of pathogenic micro-organisms has appeared for fifteen years, Dr. K. C. PAUL's succinct summary<sup>3</sup> will be of use to the general practitioner

<sup>1</sup> *Methods and Problems of Medical Education*. (Fourth and Fifth Series.) New York: Division of Medical Education, the Rockefeller Foundation. 1-2. Sent free by the Foundation on application.

<sup>2</sup> *Radiotherapy in Relation to General Medicine*. By Francis Hernaman-Johnson, M.D. Abert. Oxford Medical Publications. Oxford Medical Handbooks. London: H. Milford, Oxford University Press, 1926. (Fcap. 8vo, pp. ix + 211. 5s. net.)

<sup>3</sup> *The Carrier Problem*. By K. C. Paul, M.B., B.S. With a foreword by David Nabarro, M.D., F.R.C.P. London: Oxford Medical Publications. London: H. Milford, Oxford University Press, 1926. (Cr. 8vo, pp. xii + 102; frontispiece. 5s. net.)

in search of a clear and elementary account. The author divides carriers into contact and convalescent carriers, and each of these groups is subdivided into temporary and chronic; reference is also incidentally made to animal vectors of disease, contaminated food, milk, water, clothing, and dust; but the term "carrier" is confined to human beings. The various infections in which carriers play a part are described in successive chapters, each containing an account of the available treatment and a short bibliography. In the section on typhoid and paratyphoid fevers, McKendrick's test, and the autolysate-precipitin reaction, designed to detect the carrier state, are detailed. The carriers of streptococcal infections are divided into those of the *Streptococcus scarlatinae*, which are generally temporary—not lasting, it is said, more than two or three weeks after desquamation has begun—and those of other streptococcal infections, such as faucial, respiratory, purpural, erysipelas, and wounds. Among the diseases of unknown or doubtful etiology, influenza, epidemic encephalitis, small-pox, chicken-pox, measles, and mumps are briefly discussed.

### LORD KNUTSFORD'S MEMOIRS.

SYDNEY HOLLAND, Viscount Knutsford, tells us in the "Apologia" of his autobiography that he has called the book *In Black and White*,<sup>1</sup> not because it is inspired by a well known spirit, but because he has set down his reminiscences of fact and of fiction in black and white, and because, by a curious coincidence, these were the "colours" he wore at Trinity Hall and as a member of the Magpie Cricket Club.

Born a twin, he and his brother, now the Hon. Mr. Holland-Hibbert, were often mistaken for one another, with amusing or perplexing results. He has also been mistaken for such striking personalities as Lord Rosebery and Mr. Arthur Roberts, the comedian. He comes of good stock. His grandfather, Sir Henry Holland (1788-1873), a physician well known in the society of his day, was the son of a medical practitioner at Knutsford. Henry Holland had for his maternal grandmother a sister of Josiah Wedgwood, the potter, and Mrs. Gaskell, the novelist, was a cousin. Sydney Holland was born in 1855 and succeeded his father, the second baronet and first peer, in 1914, so that he is better known to the passing generation as Sydney Holland. His mother was the granddaughter of Sydney Smith, from whom doubtless came his Christian name and probably his keen sense of humour.

We pass over his school and college days and his experiences at the bar and as a director of dock, water, and other companies, for it is as a hospital organizer, or we might almost say dictator, that he is most interesting to the medical profession. He tells us frankly that he "drifted" into this work. Having to visit a dock workman who lay in the Poplar Hospital for Accidents, he was disgusted and distressed by what he saw there, and in 1891, on taking the chair at an annual meeting as a dock director, he recommended drastic reforms. The committee did not support him, and ended by saying that if he thought he could put things right he had better do so. He accepted this challenge and became chairman, with the result that by 1896 the hospital was rebuilt, nearly trebled in size, its reserve fund raised from £8,000 to £54,000, and was not, and had not been, in debt. When in that year he became a member of the committee of the London Hospital those who knew him prophesied—in the words of one of the staff—that "he would make things hum." Certainly events moved fast as soon as he became chairman in the same year.

There is always a risk that one who has watched the carrying out of great improvements and reforms, or has had a large share in their institution, may exaggerate the bad state of things that preceded reform. We can hardly reconcile Lord Knutsford's description of the London Hospital in 1896 with known facts. He says that "aseptic surgery was just coming in and the staff were very dubious whether it would be a blessing, or the reverse. Whenever a surgeon went round his ward he was followed by the surgery beadle, who carried such instruments as he might

be likely to require. These instruments were used, put back, and re-used on other patients with the happiest disregard of germ existence." Lister's work had then been known for some thirty years, and even if we are to understand "aseptic" in its strict technical sense, antiseptic surgery had long abolished such practices as are here described. The visiting surgical staff of the London Hospital in 1896 included such progressive surgeons as Sir Frederick Treves, C. W. Mansell Moullin, Hurry Fenwick, and F. S. Eve, while the assistant surgeons were Jonathan Hutchinson, jun., T. H. Openshaw, and H. P. Dean. It is incredible that they were so far behind the times as is implied by the above statement, or that the London can have lagged so very far behind the other general hospitals of the metropolis. We fear that Lord Knutsford's memory has here played him false and he has confused the stories he heard of earlier days with the events which came under his own notice. Nevertheless, there is no question that he achieved great things at the hospital in Mile End, and probably nobody but he could have collected the large sums needed for development. He tells us that he once received a cheque made out to the order of "The Champion Beggar," and that the bank accepted his endorsement without protest or even inquiry.

The medical and surgical staff of the hospital does not occupy much space in these memoirs and only a few of its members receive individual casual mention.

Lord Knutsford's vitality and keen zest for life are evident on every page of the book, and his cheery philosophy, despite two severe accidents and his almost total deafness, should be an example to all. He tells many good stories, some of which have stood the test of time.

His accounts of his relations with the Royal Family, and particularly with Queen Alexandra, show all concerned in the best of lights. He has been, nay, we believe that at the age of 71 he still is, a keen sportsman, and the account of his experiences with rod and gun will be full of interest for those whose joy it is to "go out and kill something." He was a distinguished oar at Cambridge, and a long-distance swimmer, and he appears to have appalled and exhausted Bernard Darwin by his methods at golf. Besides these activities his accomplishments include legerdemain and ventriloquism, and he is a proficient on that difficult instrument the clarinet.

This book is one of the few recent autobiographies which are likely to be readable in ten years' time. The concluding chapter is devoted to an eloquent and convincing defence of the voluntary hospital system.

### THE BRITISH NAVY IN ADVERSITY.

Should the "Gentleman with a Duster" ever write his *Historia Providentiae*, it is hoped that the acts of Providence which saved the British Navy from destruction in the fateful years of the American Revolution will not be overlooked. Some such thought occurs to us on reading Captain James's story of *The British Navy in Adversity*<sup>2</sup> during the War of American Independence. For if ever a providential hand guided our destinies and gave us Hood, Howe, Rodney, Kempenfeld, Barrington, and others to counteract the incompetence, corruption, jealousies, and interferences of those in high places at home, it was then. As told by Captain James, the story of the amphibious warfare against the American colonists from Canada to Georgia, and against the French and Spanish fleets from the Balearic Islands and Gibraltar to the English Channel, and in the West and East Indies during the years 1762 to 1783, is a thrilling page in the history of the British Empire.

The book's interest to medical readers lies in the occasional references to operations and to expeditions being abandoned on account of sickness on board the ships, not only in the unhealthy tropics, but also in home waters. The enemy allied fleets suffered severely and were prevented by epidemics from effectually undertaking operations against the British when the latter were more or less at their

<sup>1</sup> *In Black and White*. By Sydney Holland, Viscount Knutsford. London: E. Arnold. 1926. (Med. 8vo, pp. viii + 392; 3 plates. 21s. net.)

<sup>2</sup> *The British Navy in Adversity: A Study of the War of American Independence*. By Captain W. M. James, C.B., R.N. London: Longmans, Green and Co., Ltd. 1926. (Med. 8vo, pp. xvi + 459; 15 maps, 28 diagrammatic sketches. 25s. net.)

mercy. In 1779, for example, the French commander-in-chief, in bemoaning the misfortune caused by the failure of the Spanish fleet to join him in time, wrote that "a worse calamity still is this terrible epidemic which is weakening my ships." We are not told what the epidemic was, but three years later Howe's fleet was similarly incapacitated by "an epidemic disorder called the influenza," which caused great havoc amongst his crews while cruising off the Dutch coast. Other points of medical interest are the occasional references to Sir Gilbert Blane, Rodney's physician during the operations of the fleet in the West Indies, and his comments on the battles fought in these waters.

Although medical information is scanty and vague, Captain James's volume is one that should be read by everyone. It throws much light on the history of the period to which it refers, and teaches many lessons, over which statesmen, politicians, and the man in the street might well ponder. The graphic illustrations of the naval battles make it easy for the ordinary reader to follow the narrative, and add much to the interest of the book.

### NOTES ON BOOKS.

To write of a highly technical and specialized subject in such a manner as to be comprehensible to those who know little of the foundations upon which it is based is by no means easy, and the task becomes the more difficult when the writing has to form the basis of delicate and practical procedures, a true acquaintance with which can only be acquired through the experience of actual practice. Mr. M. H. WHITING, in his manual on *Ophthalmic Nursing*,<sup>8</sup> has succeeded in presenting his subject in a manner which should prove to be of considerable value to his particular audience, and should be not without its uses to the wider circle of students and practitioners of ophthalmology. No description has been given of the procedures common to all types of nursing; the book is confined to the special methods adopted in the medical and surgical treatment of diseases of the eye. The methods advised are without exception sound; their description is concise, explicit, and to the point; and each is treated with an amount of detail which is surprising considering the size of the book. The fact that they are based upon the practice evolved and adopted at Moorfields Eye Hospital, which has maintained its world position in all things ophthalmological for over a century, is guarantee of their value, and provides sufficient justification for their publication. In view of its purpose, and considering its price, the book is well printed, well indexed, and lucidly and profusely illustrated.

The first and second volumes of *Tabulae Biologicae*<sup>7</sup> have already been mentioned in the JOURNAL (1926, i, 832), and the third volume, which has just appeared, continues the useful task of collecting into a single work of reference as many biological data as are available. The first half of this volume is occupied chiefly with organic chemistry and biochemistry, and the common chemical and physical constants are given for some thousands of such compounds as are of interest to the biochemist and pharmacologist. Another large section of the book is devoted to anatomical data, and tables of lengths and weights of the human body and its parts are given. Towards the end of the volume are some useful pharmacological data. For example, the minimum lethal doses of some hundreds of compounds are given. These are merely samples of the data presented in the volume. It is needless to say that these data are of very varying value, for biological science is only slowly attaining to the status of an exact science, and reliable data are unfortunately scarce. The publication will, however, be found a very great convenience by all workers in the biological sciences.

Dr. J. T. KING's book *Basal Metabolism*<sup>6</sup> gives a short and straightforward account of the teaching of modern physiologists concerning the body metabolism in general and of the application to human disease of physiological methods of determining the metabolic rate. Within recent years a great volume of research into human metabolism has been contributed to scientific journals, but there have not been many attempts to

bring the new views to the notice of the general physician. This is one of the chief aims of Dr. King's book, and one he has succeeded in attaining, for he has given a very readable version of the problem. His eight chapters deal successively with historical questions, general physiology, the pharmacology of heat production, chemical questions, the anatomy of the thyroid gland, metabolism in hyperthyroidism and in hypothyroidism, and in other conditions. The book will be of more interest to readers who want information as to the meaning and value of metabolic tests than to those who wish to learn to do them, because the author does not go into much detail in his description of methods and apparatus.

*Practical Pharmacognosy*,<sup>9</sup> by T. E. WALLIS, is a textbook prepared for students in the School of Pharmacy of the Pharmaceutical Society. Professor GREENISH points out in a preface that it has been prepared with great care, and that a large proportion of the matter printed is based on original observations by the author. The book is divided into two parts. The first contains instructions for a course of seventeen practical classes in the examination of the macroscopic and microscopic characters of plants used in medicine, and the second a summary of the characters by which the medicinal plants may be recognized. The illustrations are an outstanding feature of the work. There are eighty-one excellent drawings of plants, of which many are original. The book provides a concise and clear introduction to the science of pharmacognosy, and is well adapted to the needs of the student of pharmacy.

We have received a copy of the fifth issue of *L'Année médicale pratique*,<sup>10</sup> edited by Dr. CAMILLE LIAN, supported by a staff of forty-five contributors. It contains in alphabetical order a concise account of the principal contributions to medical literature in the widest sense of the term. A new feature of the present issue is that representatives of the Argentine Republic, Belgium, Jugo-Slavia, and Switzerland figure among the contributors, with articles outlining the progress of medicine in their respective countries. The preface states that in subsequent issues similar contributions will be made by representatives from Holland, Italy, Rumania, Spain, and Uruguay.

The monograph on the stages of development of pulmonary tuberculosis<sup>11</sup> edited by Dr. CHRISTOPH HARMS, director of the hospital for diseases of the lungs at Mannheim, consists of three parts. The first, which deals with the recognition of the various stages of pulmonary tuberculosis, is illustrated by serial skiagrams of thirty-six cases. The second part is devoted to the prophylactic and curative treatment of pulmonary tuberculosis in the special welfare centre and hospital for diseases of the lungs at Mannheim. The third part is concerned with the administrative measures for combating tuberculosis in Baden generally and in Mannheim in particular. An appendix contains a list of the scientific publications of the Mannheim hospital and welfare centre.

### PREPARATIONS AND APPLIANCES.

*Campemyl*. "CAMPHEMYL" is an ingeniously devised preparation of camphor, suitable for hypodermic administration. Each ampoule of 1 c.cm. contains 0.1 gram natural camphor dissolved in a mixture of methyl urethane, mono-ethyl urea and distilled water. The solution is clear and colourless and of low viscosity. The last property makes it possible to inject the solution through a fine-bore needle. The therapeutic effects of this preparation are of a character similar to those produced by solutions of camphor in oil, but the makers claim that campemyl is much less irritating and does not produce camphor abscesses. The drug is recommended for intravenous as well as subcutaneous administration. The intravenous injection of any drug should, of course, be performed with reasonable caution, and such caution is particularly necessary in the case of "campemyl," because the camphor is precipitated when the solution is diluted in the blood stream. Intravenous injections should therefore be given slowly to ensure thorough mixing with the blood. Clinical and pharmacological trials, communicated to us by the makers, show that, provided due caution is exercised, intravenous injections of campemyl can produce a beneficial action in cases of shock, and do not produce undesirable after-effects. The makers are the Society of Chemical Industry at Basle, and the agents in this country are the Clayton Aniline Company, 40, Southwark Street, London, S.E.1.

<sup>7</sup> *Tabulae Biologicae*. By Maurice H. Whiting, O.B.E., M.B., B.Ch. (Camb.), F.R.C.S. With an introduction by Sir John Parsons, F.R.C.S., F.R.S. London: J. and A. Churchill, 1926. (Cr. 8vo, pp. xii+173; 152 figures. 5s. net.)

<sup>8</sup> *Ophthalmic Nursing*. Edited by C. Oppenheimer and L. Pincussen; with contributions by 45 contributors. In four volumes. Vol. III. Berlin: W. Junk, 1926. (Cr. 8vo, pp. vi+222; half calf, 13 2s.; sewed, 13 2s.)

### REST FOR ACUTE POLIOMYELITIS.

THERE are, unfortunately, unmistakable indications that the epidemic of acute poliomyelitis, which it has for some years been feared might occur in this country, is on the move. The disease has borne more than one name; it was originally known as infantile paralysis, but as it became recognized that it sometimes affected adults the pathological name of anterior poliomyelitis was substituted. Later still it was established that in some of the cases observed during epidemics the lesions were found in other parts of the central nervous system, including the cerebrum, and the cumbersome title of "anterior myelo-encephalitis" was introduced by Lovett. Usually, however, the stress of the infection falls on the spinal cord and the brain escapes, though it is probable that a large proportion of the fatal cases are due to its involvement. The disease is said to be more prevalent in the summer, but the present epidemic in this country seems to have gathered strength during the last three months. A table of notified cases prepared by the Ministry of Health is published in our Parliamentary Notes (p. 966); they are shown under poliomyelitis and polio-encephalitis respectively, but we have added them together to give a better view of the prevalence of the disease, for the infection of the brain and of the cord seems undoubtedly to be due to the same agent. It will be seen that the cases notified from the beginning of May to the end of October have numbered altogether 875, and have risen from 21 in the first month to 373 in October. Cases have occurred in greatest number in Thanet and in parts of the Midlands, including Leicestershire and Rutland.

The fear that an epidemic might occur in this country was in large measure due to the experience of the United States, and also of the Scandinavian peninsula and of Central Germany. In 1894 there was an epidemic in the New England State of Vermont, and at least thirteen epidemics, comprising over 18,000 cases, with an average death rate of 20.7 per cent., occurred during the next twenty years, culminating in the terrible outbreak in the City and State of New York in 1916; in it 13,223 persons were attacked, and the death rate was over 25 per cent. The Ministry of Health, in a memorandum issued at the beginning of 1925, puts the fatality rate much lower, and says that it is commonly 10 to 12 per cent. of the attacks. It is estimated that complete recovery occurs perhaps in one-fourth of the survivors, but the remainder are to a greater or less degree the victims of a lifelong disability.

The clinical stages of the disease have been divided into three: the acute, which has usually subsided within four to six weeks; the recovery stage, which extends approximately to the end of the second year; and the chronic stage, from the third year onwards. It is admitted on all hands that the diagnosis of the disease in the acute stage may be extremely difficult, unless helped by a knowledge that cases are occurring

in the area. If that be so, treatment should be instituted on suspicion, for a few weeks' rest can do the child no harm.

Of the signs which may be considered especially significant three have been found to be remarkably constant—stiffness in the neck, spontaneous pain in the back and limbs, and marked tenderness of the limbs; this last is held to be the most important. If the patient is carefully watched during the early irritative stage transient nystagmus, twitchings and paresis of limbs or of groups of muscles may often be recognized. At the onset twitchings and tremors are generally observed even in mild cases, and convulsions occasionally in young children. At this stage the knee-jerk may be exaggerated, but afterwards it disappears, as do other reflexes in the limbs. Definite paralysis, which is usually of the flaccid type, follows the primary symptoms and affects one or more groups of muscles, especially of the limbs, but it may involve any part of the muscular system. It is important to remember that the acute stage may not be very marked, and it is quite common for parents in the out-patient room to assert that the child has never been ill.

We have no specific, but Medicine is not helpless; a great deal can be done by wise treatment to mitigate the dire consequences of the attack. Treatment seems to be summed up in one word—rest. Sir Robert Jones, in an address published in our columns in 1922 (vol. i, p. 706), said that during the acute stage of onset we must trust entirely to rest to protect the muscles which are weak, and so prevent the oncoming of deformity. During the acute stage the two things to do were, he said, to keep the head and spine at rest in an apparatus so constructed that nursing was rendered harmless, and to allow nothing to happen which might conceivably frighten the child. The hip and spine should be kept absolutely at rest, in obedience to the general law applicable to inflamed structures. Rigid fixation of the hip and spine relieves pain; but even if the pain is slight rest is imperative for physiological reasons.

The deformities that usually have to be guarded against are contraction of the feet in plantar flexion, flexion of the hips and knees, adduction of the shoulder, and curvature of the spine. The next principle is that as recovery begins to take place the relaxation should be lessened by small degrees, regulated by the patient's ability to make use of the muscle in its extended range. A muscle over-exercised begins to lose power, and a weak muscle must not be over-taxed. While active mischief is present in the cord electricity and massage should be avoided, for it is not physiological to irritate and stimulate peripheral ends of nerves connected with inflamed centres. Such practice is irrational, cruel, and reactionary. Sir Robert Jones condemned also applications of heat and cold. Later on the principle to be observed was that a muscle submitted to stretching will lose its function and that a distinction must be drawn between a muscle paralysed by destruction of its governing cell and a muscle disabled and impotent from overstretching.

It has been established that the disease is infectious, though there are plenty of cases to prove that it may not be transmitted even by very intimate association. Though the micro-organism concerned has not been isolated, it is believed to be a filter-passer. The Ministry of Health expresses the general opinion when it says that it is important to isolate all patients in the acute stage, whether the manifestation of illness is

slight or severe. This offers the best hope of preventing spread; though it has to be remembered that the disease may be propagated by unsuspected carriers.

The need for isolation gives point to the warning Lord Dawson of Penn and Dr. James Collier have given in the public press against the action taken in closing Uppingham School, which has meant sending about 500 boys to their homes in all parts of the country. The school authorities and their medical advisers were in a very difficult position, but we fear that they have taken too sanguine a view in supposing that the expedient of closing the school for a fortnight will be sufficient, though possibly it may. The incubation period is said to be usually four or five days, but in very few diseases can the incubation period be rigidly defined, and cases are on record in which in this disease it has been much longer. Lord Dawson and Dr. Collier, both in their published warning and in the circulars which have been issued to parents of children at Broadstairs schools, lay stress on the fact that a boarding school can easily be made a self-contained community, can isolate itself from the outside world, and completely control the activity of its inmates. This policy has been applied at Broadstairs, where a number of cases occurred in the boarding schools for both boys and girls. It appears to have been successful there, for no fresh cases have been reported in that district for a fortnight. To send a whole school home for two weeks, Lord Dawson and Dr. Collier point out, does not mean that the problem will be over for the school when it reopens. The same precautions will have to be taken as were taken at Broadstairs from the onset of the outbreak. We entirely accept their opinion that to send several hundred boys to their scattered homes, where it is impossible to watch them with the same care as at school, is to run the risk of extending the disease throughout the country. In this connexion a very great responsibility rests upon parents. The disease is no respecter of classes, and parents, in the interests of their own children as well as of the public, should loyally abide by the policy determined by the school authorities on the recommendation of their medical advisers. Lord Dawson and Dr. Collier mention that an instance has just come to light of a girl being infected with the disease by a boy who was taken home by his parents from one of the Broadstairs schools. The sound policy from all points of view and in the interests of everyone is to isolate the patients, and to keep all other inmates of the school under systematic daily medical supervision, not forgetting that adults may be attacked.

### THE ADMINISTRATION OF DRUGS OF ADDICTION.

THE judgement of the Divisional Court of the King's Bench Division (the Lord Chief Justice, Mr. Justice Avory, and Mr. Justice Salter) allowing the appeal of Dr. G. C. Kingsbury, who is both a practising barrister and a registered medical practitioner, against a conviction by the late Lord Mayor of London (Sir William Pyke) is of great importance to the medical profession and the public. The hearing before the Lord Mayor was reported briefly in the JOURNAL of March 13th last (p. 509), and in the present issue we give a report of the appeal on page 964. Dr. Kingsbury was charged with failing to enter in a register or day-book the name and address of a patient whom he was endeavouring to cure of the morphine habit by a gradual reduction of doses. It was admitted that the

name and address of the patient had not been entered anywhere; but the defence was that Dr. Kingsbury had done all that the law required of him inasmuch as (1) the regulation and schedule relied upon were *ultra vires* as not being authorized by the section of the Dangerous Drugs Act, 1920, under which the regulation purported to be made; and (2) that, in any event, in this case Dr. Kingsbury did not "supply" the drug, but was protected by the proviso "that administration of the drugs by or under the direct personal supervision of a duly qualified medical practitioner shall not be deemed to be supplying the drug within the meaning of the regulations," and was therefore under no obligation to comply with the provisions attached to "supplying," including that which requires the entry of the name and address of the person supplied. The former of these issues was not determined by the court, as the latter issue was, by itself, sufficient for the judgement; but whether the particular regulation in question be *ultra vires* or *intra vires*, it is satisfactory to know that the courts will scrutinize closely the action of Government departments in their exercise of that power of making regulations under Acts of Parliament which modern legislation has a tendency to give them. To remove to the sphere of administration matters which ought to be the subject of legislation is an easy procedure which cannot be watched without some anxiety, and there is evidence to support the opinion that the method has already been carried too far.

The main importance of the judgement of the Divisional Court lies, however, in the interpretation of what constitutes "administration" of dangerous drugs as distinguished from their "supply," and of the meaning of the phrase, "under the direct personal supervision of a duly qualified medical practitioner." The Lord Mayor had held that the Director of Public Prosecutions was right in contending that the words "administration of the drug by a duly qualified medical practitioner" meant that the doctor must administer every dose by his own hand, and that "administration under the direct personal supervision of a duly qualified medical practitioner" meant that the doctor must be present and either see the patient administer each and every dose to himself, or see the nurse or other person administer such dose to the patient. A few searching questions from the Divisional Court, however, led the respondent's counsel to abandon this strict interpretation; he admitted, indeed, that such an interpretation would be in certain conditions "oppressive." Counsel contended further that the word "administration" was confined to cases of emergency, as contrasted with regular supply. The court, however, held that it was "as impossible to limit the words of the proviso to cases of emergency as it was to limit personal supervision to cases where the doctor was personally present," and declared that, once this limited meaning had gone, on the facts of this case there had been personal supervision and the proviso applied. Dr. Kingsbury's appeal was therefore allowed, with costs.

No opinion was expressed as to whether the regulations should be amended; that question was not one for the court, but for the Government department concerned. It is to be hoped that any proposed amendment will be very closely watched and very fully considered by all concerned. But there would not appear to be any good reason for disturbing the regulations as now interpreted, for it must be remembered that the court has not given any definition of

what constitutes "direct personal supervision" of drugs of addiction. It has merely destroyed the narrow interpretation put on these words by the Home Office, and has declared in a particular case that the facts showed that there had been such supervision. The facts appear to have been (1) that Dr. [redacted] had himself seen the patient over [redacted] that on each occasion he had given him only sufficient doses of the drug to last until his next visit. It does not follow that there may not be other cases in which, though the facts are different, it may still be held that there was nevertheless "direct personal supervision," but it would seem that such supervision must be recognized at any rate in cases where the facts are substantially the same. This at once makes the regulations in question less oppressive and less troublesome, and in a wide class of case preserves to the medical practitioner that right, which he rates so highly, of not being compelled to disclose the identity of those who have consulted him or the nature of any condition for which he is treating them.

#### SKIN, HAIR, AND EVOLUTION.

PROFESSOR H. J. FLEURE, who has established his reputation as one of the sanest and most stimulating thinkers and writers on anthropology, devoted his Malcolm Morris Memorial Lecture, which is published in an abridged form at page 953, to a consideration of the light that may be thrown on the evolution of man by a study of the special characteristics of the skin and hair in different races. The lecture may be said to deal with a special case of the general proposition put forward by him in his presidential address to the Section of Anthropology of the British Association at Oxford this year. Professor Fleure is aiming at encouraging the study of human race types, not according to the established differences of form and colour, but from the evolutionary standpoint. At Oxford he said that early modern man had provisionally been placed geographically in the zone from the Atlantic edge of the Sahara to Persia, and that there was a fairly large population not all exactly alike. He believed them to have been more or less brown-skinned, with blackish hair and brown eyes, with jaws and brow ridges much reduced from the conditions known in many of the early forms of man, and with heads almost balancing on the vertebral column, though the erect posture had not been attained in all cases. He supposed them to have lived in the days of the retreat of the ice sheets, after the last maximum phase of the Great Ice Age, and to have inhabited the Sahara, Arabia, and Mesopotamia, then rather cool grasslands. In the course of his Oxford address he elaborated the theory that the development of man depended on hereditary factors of a conservative nature and on environmental influences which have changed with climate, food, and equipment. Among the evolutionary changes which he believes to have had great influence is the lengthening of pre-natal life from about 220 to 280 days, with consequent continuance of growth of brain and delay of hardening of skull, permitting an increase in skull volume continuing during infancy, so demanding lengthened maternal care. The postponement of fixation of characters and the maintenance of more or less embryonic conditions, he thinks, resulted in the unfolding of new features in response to opening up of new possibilities, and thus became a cardinal factor for the human race. Further, the prolongation of infancy had probably contributed to differentiating women's work from men's, and may have accompanied the growth of the hunting habit in man, woman remaining more a gatherer. Men thus came to command two mutually supplementary

types of food; and this may have been a valuable step forward at that stage of evolution. It would involve also an enrichment of social life, though he did not think that human society had resulted so much from the coming together of individuals as from the liberation bit by bit of individual initiative within groups. In his Malcolm Morris Lecture he insists on the importance of variation of weather conditions, and observes that the best conditions for bodily efficiency appear not to be very different from those of our present British climate, and for mental efficiency our rather cool but not too bitterly cold spells. He supposes that from the Central Mediterranean communities in, say, the Sahara man drifted south towards Central Africa and eastwards into Asia, and eventually northward into Europe. Towards the south he found climatic conditions which made essential evolutionary changes favouring the dissipation of bodily heat. Towards the north he found climatic conditions developing as the ice retreated which by their variability, by the absence of extremes of temperature, and incidentally of the long winters of continuous frost and snow, favoured mental development. It will be seen how ingeniously he brings the skin and hair characteristics of different peoples to support his main thesis.

#### THE LEAD TREATMENT OF CANCER.

It was in the autumn of 1922 that Professor W. Blair Bell published his first paper on the results then achieved by him and his colleagues at Liverpool in the treatment of advanced cases of cancer by the administration of lead preparations. From time to time during the following three years we published notes on these investigations into the effect of lead in colloidal form upon cancerous tissues, and almost exactly a year ago the late Dr. J. G. Adami outlined for the benefit of our readers the story of the work so far as it had then gone (November 21st, 1925, p. 978). The occasion of his letter was the widespread public interest in a paper read by Professor Blair Bell to the Toronto Academy of Medicine. It may be convenient if we now recall some of the leading references to this matter during the present year. On March 6th (p. 431) we published a memorandum by the Liverpool Cancer Research Committee, answering criticisms in regard to disclosure of the method of preparation of the material used in these investigations, and defining fully the position of Professor Blair Bell, in anticipation of the address he was to deliver before the Medical Society of London on the use of lead in the treatment of malignant disease. That address and the discussion which followed were reported in our issue of March 27th (p. 568), and on April 17th (p. 687) we printed the full text, with microphotographs. The next event of importance was the third morning session of the Section of Medicine at the British Medical Association's Annual Meeting at Nottingham in July, which had been set apart for a full presentation of the work accomplished by Professor Blair Bell and his colleagues during the preceding five years. He himself was prevented by illness from attending, and in his absence Dr. Adami introduced the subject and read Professor Bell's opening paper, describing the constitution and methods of work of the Liverpool Cancer Research Organization, and concluding with a brief statement of his views on the nature of malignant neoplasia. The full report of this symposium, with illustrative plates, appears in our present issue, the material having been revised and amplified by the several authors. In the concluding paper of the series Professor Blair Bell has endeavoured to draw a composite picture of the work and to co-ordinate the main points brought out by his colleagues. It appears from the latter part of this that the situation with regard to the distribution of lead colloid is at the moment rather complicated. Some time ago

British Colloids Limited was authorized to make a suspension of lead after representatives of the firm had been to Liverpool to learn all that could be shown them. Unfortunately, a modification, suggested by the chief chemist to the company in order to prevent the formation of lead hydroxide, has been found to produce also a toxic substance (possibly a proteose) giving rise to severe rigors, lowering of the blood pressure, and other untoward symptoms. In these circumstances (Professor Blair Bell informs us) the Liverpool committee has felt it advisable to withdraw the permission given to the company to issue any more supplies for the present. It is hoped, however, that before long the preparations of lead such as those made by Professor Lewis and his associates in Liverpool will be stabilized by the addition of gelatin and so made available for general distribution; in the meanwhile certain emergency measures are being taken to maintain supplies for patients outside Liverpool who are already undergoing a course of this treatment.

#### THE PREVENTION OF HEART DISEASE.

THE Children's Home Hospital at Strathblane in the West of Scotland, which was opened originally at Aberfoyle twenty-three years ago for the treatment of children suffering from tuberculous disease of the bones and joints, has carried on its beneficent work since that time with conspicuous success. The children received into the home come from Glasgow hospitals and invalid schools. The charges for their treatment may in some cases be defrayed by public authorities, and some parents sending their children by private arrangement make contributions according to their means, but these payments meet only a fraction of the cost of maintenance; the home is essentially a medical charity. Encouraged by what it has been enabled to do in the past on behalf of tuberculous children, the committee of management of the home has recently had it in mind to extend its usefulness in a new direction to which medical opinion is pointing. It has desired to undertake the care of boys and girls suffering from acute rheumatism and its complications, especially as affecting the heart. In entertaining this design it has had the sympathetic interest of Professor Leonard Findlay, professor of pediatrics in the University of Glasgow; Dr. A. S. M. Macgregor, medical officer of health for the city of Glasgow; Dr. E. T. Roberts, principal school medical officer of the Glasgow Education Authority; and Dr. George A. Allan, assistant physician to the Western Infirmary, Glasgow, and a member of the British Medical Association committee on rheumatic heart disease in children. The committee of management of the hospital announces that it is now in a position to realize its laudable ambition. By the generosity of a lady it has been placed in possession of £12,000, to be devoted to the equipment and partial endowment, at the home, of twelve extra beds for rheumatism and heart disease. The committee is now appealing to the public for a further capital sum of £10,000, to complete the endowment of the beds and to place the enterprise on a sure footing. The appeal should not be in vain. The new field of work is rich with promise; its importance, on both the preventive and curative sides, is of the first order, as has been urged in the pages of the JOURNAL. The home, as expanded, will be the first of its kind in the West of Scotland, and one of the first in the country generally. Professor Leonard Findlay will act as its consulting physician. It is pertinent to recall that at a symposium of medical officers held in Glasgow in February last on the prevention of heart disease, the principal speakers included Dr. Roberts and Dr. G. A. Allan, and Dr. A. K. Chalmers, Dr. Macgregor's predecessor in office, then medical officer of health of the city. It may perhaps be permitted to conjecture some degree of causal relationship between the words spoken by them in Glasgow at that

time and the facilities for the treatment of rheumatism and the prevention of heart disease now foreshadowed at Strathblane. Be that as it may, the West of Scotland is most substantially indebted to the generous and enlightened donor of the means by which treatment and prevention have been made possible.

#### EFFECT OF TREATMENT ON THE WASSERMANN REACTION.

THE Medical Research Council has issued this week a report on some investigations into the effect of treatment on the Wassermann reaction of syphilitic patients.<sup>1</sup> The observations were made at the venereal clinic of the Liverpool Royal Infirmary by Professor E. Glynn and Drs. R. E. Roberts and Phoebe M. Bigland, and extended over the period from April, 1918, to December, 1923. The course of treatment consisted of an admission treatment with 914 and grey oil, and, after an interval, continuation treatment with mercury. The Wassermann technique used was No. 4 of the Medical Research Council; and the reagents were distributed by a semi-automatic battery of twelve syringes devised by Professor Glynn. The observers regret that out of 3,429 patients only 711 were available for studying the effect of treatment. This was due to inadequate attendance at the clinic, due partly to the fact that 40 per cent. of the patients were "wanderers," such as sailors; it appears, however, that the attendance of people with fixed residence was not much better. The investigations confirmed the vital importance of treating syphilis at once and thoroughly, and led to some unexpected conclusions about routine treatment with mercury. The success of the standard admission course in producing a negative Wassermann test was found to depend on two factors: first, on the result given by the Wassermann test on admission, the success varying from 92 to 78 and 52 per cent. according as this test was negative, partially positive, or positive; secondly, the more prolonged the period between primary lesion and treatment at the clinic the less the success. The results of the admission course were apparently uninfluenced by the fact that some of the patients had received some measure of treatment elsewhere. It was found that novarsenobenzol was slightly less efficient, and also less toxic, than novarsenobillon and neokharsivan. There was an unexpected failure of the admission course to produce a negative Wassermann reaction in some patients. The negative or partial Wassermann reaction in early syphilis might sometimes become positive about the beginning of a salvarsan course, and negative again if the course was prolonged. Some of the failures may have been due to faulty brands of the drug, the existence of which was noted by Colonel Harrison in 1921. Standardization has now eliminated all faulty brands of British manufacture. The unexpected conclusions about treatment with mercury were reached only after an attempt had been made to eliminate all possible fallacies. The observers found that, in contrast with its usual success in the treatment of clinically active syphilis, mercury frequently fails in cases of Wassermann-negative "latent" or quiescent syphilis, and that this failure is due to the different pathological condition treated. Mercury attacks the spirochaetes when circulating in the blood, but not the inaccessible residual spirochaetes protected in fibrotic lesions or in indurated lymph glands, spleen, or testis. Not only so; mercury increases the Wassermann relapse incidence, partly, perhaps, because it produces mercury-resistant spirochaetes, and possibly subsequently provokes them into activity; this is most probably to be accounted for by supposing that it depresses the immunity of the patient, possibly in some instances by damaging his general

<sup>1</sup> Medical Research Council. Special Report Series No. 107. H.M. Stationery Office, or through any bookseller, price 3s. 6d. net.

health. The observers believe that salvarsan, while it is a more potent spirochaetocide than mercury, does not develop resistant strains of spirochaetes under prolonged administration. Consequently they consider that extra courses of salvarsan will be more successful than mercury in preventing relapses as indicated by the Wassermann reaction and in destroying any residual spirochaetes in Wassermann-negative "latent" or quiescent syphilis. The examination of the possible objections that may be brought against their views is developed in an interesting way; probably the general opinion will be that an investigation of a larger number of cases over a longer period is needed before the conclusions at which they have arrived are fully accepted.

#### WELFARE OF THE BLIND.

THE sixth annual report of the Advisory Committee on the Welfare of the Blind to the Minister of Health<sup>1</sup> deals with the years 1924-26. Full advantage appears to be taken of the provision of the Blind Persons Act of 1920 whereby pensions are provided for the blind over the age of 50 years; there are now 13,663 such pensioners, which number includes all the blind within the age group except 10 per cent., who are presumed to have private means. The moneys expended by local authorities on the welfare of the blind show a large increase: for the five years commencing 1921-22 the totals have been £14,671, £47,106, £71,805, £102,910, £127,593, so that it has been increased almost tenfold in this short period. Much of this money has been expended through voluntary agencies, and it is noteworthy in this connexion that the provision of public money has not diminished the flow of private benefactions; during the year 1922-23 the total income from voluntary sources of 130 agencies recognized by the Ministry was £378,535, while for the succeeding year it has increased to £401,701. This is taken as strong approval of the triple partnership of the State, the local authorities, and the voluntary societies in the care of the blind. Attention is called to the important provision of the Public Health Act of 1925 whereby local authorities have the power to make such arrangements as they may think desirable for assisting in the prevention of blindness, and in particular for the treatment of persons ordinarily resident within their area suffering from any disease of or injury to the eyes. This is an important provision, and the possibilities of exploiting it for the prevention of blindness, especially in industrial areas, might well be investigated. The register of the blind shows an increase in the totals and in the ratio to the general population. In 1919 the total number of blind known was 25,840, with a ratio of 1 to 1,396 of the general population. In 1925 the figures were respectively 42,140 and 1 to 911. The ratio varies widely in different parts of the country—for example, in Northumberland it is 1 to 2,301, whereas in Exeter it is as high as 1 to 422. Possibly the existence of a large blind school in a small city like Exeter will account for the latter figure. The steady increase in the number of known blind is accounted for by better information, much more care being taken to find out blind persons, both indigent and others; further, there is a higher average expectation of life in the general population, and this will mean an increase in the number of cases of blindness due to age changes. That there is truth in this is shown by the fact that in the age group under 21 there was an increase between 1923 and 1925 of only 128, whereas in the same period there was a total increase of 4,521 in the age groups over 50 years. The heavy losses made by some of the workshops for the blind is noted. The difficulty of running such shops at anything but a loss is admitted, but better results could, it is

thought, be obtained if there were better salesmanship, and especially co-operative selling. Experience has also shown that a judicious dilution of blind with sighted labour will secure substantial reduction of trade losses. Attention is drawn to the inadequate provision made for the training of myopic and partially blind children. It is estimated that there are at least 5,000 such in the country, and the available accommodation now existing in myope classes is only 1,600, of which some 600 are in London. The committee expresses the opinion that any restriction in the development of myope classes or sight conservation classes would be a very regrettable and in the long run an uneconomical measure, and it hopes that educational authorities will proceed to the full development of the facilities for the education of children with defective sight. A word in criticism of the "format" of the pamphlet may perhaps be permissible. Two pages conveying information to which it is desired to draw special attention are set up in italics. This type is much more difficult to read in bulk than ordinary type, particularly when the paper is so thin that the impress of the type on the reverse page is visible. Thus the attempt to give emphasis by printing whole passages in italics may defeat its own end.

#### GASTRIC AND DUODENAL ULCERS.

To the *Archives des Maladies de l'Appareil Digestif et de la Nutrition* for July last Dr. A. F. Hurst contributed an interesting historical study of gastric and duodenal ulcers. The first description of gastric ulcer he finds in the *De Medica Historia Mirabili* of Marcellus Donatus of Mantua (A.D. 1586). In 1670 Mme de La Fayette, lady-in-waiting to the Duchess of Orleans, daughter of Charles I, gave a vivid description of the symptoms of perforated gastric ulcer in her royal mistress. This description shows clearly the cause of death, and refutes the charge of poisoning alleged against the Chevalier de Lorraine. In 1729 Christopher Rawlinson brought before the Royal Society his observations on a case of perforated gastric ulcer; and towards the end of the same century further publications were made by Bleuland at Leyden, and by Matthew Baillie in London. In the nineteenth century researches were made by John Abercrombie of Edinburgh and by Cruveilhier, whose name is often given to gastric ulcer in French literature. Abercrombie's work has the merit of describing duodenal as well as gastric ulcer. Neither the memoir of Cruveilhier in 1856 nor the monograph of Brinton in 1857 contains reference to duodenal ulcer, though this variety had been found associated with gastric ulcers by Morgagni in 1737, and a case had been mentioned by Sir George Baker in 1772. Perforated duodenal ulcer was described in 1793 by Jacopo Penada of Padua. The case had been forgotten until Malloch republished it in the volume issued in honour of the seventieth birthday of Sir William Osler; Dr. Hurst gives a full quotation of the description of the case. Abercrombie's suggestion that the symptoms of duodenal ulcer were sufficiently precise to render diagnosis possible during life was confirmed by Bucquoy in 1887; and Dr. Hurst regards it as remarkable that the works of these two investigators have been almost entirely forgotten, so much so that at the beginning of the present century duodenal ulcer was still regarded as a rare disease, difficult of diagnosis. The first gastro-enterostomy for chronic gastric ulcer was performed by Doyen in 1892. Codivilla in 1893 performed gastro-jejunostomy for stenosis due to duodenal ulcer; but it was left for Moynihan, in 1901 and later, in publishing his surgical researches, to give for the first time a complete description of the characteristic symptoms of duodenal ulcer. After alluding to observations by Dieulafoy, Hale-White, and others, Dr. Hurst concludes his study with the remarks that for the first twenty years of this century we owed our great advance

<sup>1</sup> Ministry of Health. Sixth Report of the Advisory Committee on the Welfare of the Blind, 1924-26. London: H.M. Stationery Office, 1926. Price 9d. net.

in knowledge of gastric and duodenal ulcers entirely to the surgeon. In the last five years the biochemists and radiologists have come to our assistance; but it is to the general practitioner and the physician that we must look in the future for early diagnosis, and for preventive and curative treatment.

#### MEDICAL RESEARCH IN SOUTH AFRICA.

New departments for medical entomology and biochemistry have been added to the research division of the South African Institute for Medical Research at Johannesburg, and the department of bacteriology has been extended by the establishment of a branch for plague research. Field investigations into plague have also been instituted in a camp in the Orange, Free State Province. A survey of the mosquito and molluscan carriers of malaria and bilharzia respectively has been commenced. Sir Spencer Lister, who (as recorded in our issue of October 9th, p. 659) became director of the institute last August, when Dr. W. Watkins-Pitchford retired through ill health, has issued the annual report of the institute for the year ending March 31st, 1926. He states that the cost of maintenance was £35,768; this was an increase of more than £6,000 over that of the previous year, and was due to the process of enlargement, which is continuing. In the part of the institute concerned with routine pathological examinations for the Government, hospitals, municipalities, the mining industry, and medical practitioners, the expenditure was fully met by the revenue. A new arrangement with the Witwatersrand University has made the institute responsible for staffing and developing the department of pathology and bacteriology of the medical school, and the pathological and parasitological collections in the museum of the institute are being used for teaching purposes. The researches carried on by the staff of the institute during the year include an investigation into the susceptibility of various veld animals to plague, several of them having been found to constitute a possible source of the spread of this disease. Entomological studies are being made of the fleas and other ectoparasites of the small carnivora of the veld with a view to tracing their connexion with the spread of plague. Continuing the study of miner's phthisis on the Witwatersrand, evidence has been obtained suggesting that tuberculosis is now the dominating factor in the disabling and fatal type of this disease, and that environmental conditions have, therefore, to be taken into account. It appears probable that inhaled dust facilitates the occurrence of infections—tuberculous or otherwise—before a recognizable clinical silicosis develops. The work of the routine division has increased, 52,844 investigations having been made during the year ending December 31st, 1925, an advance of 11,011 on the figures for the previous year. It is added that medical practitioners are realizing to a greater extent the value of the hydatid complement fixation test, and there is growing appreciation of the importance of blood sugar and blood urea investigations.

#### THE HEALTH OF NEW ZEALAND.

THE last annual report of the Director-General of Public Health in New Zealand is for the period from April 1st, 1925, to March 31st, 1926. It contains separate parts written by the directors of a variety of public health activities, and the Director-General, Dr. Valentine, provides a general survey. The part which is of most general interest is Dr. McKibbin's report, in which the vital statistics of the Dominion are tabulated. Exclusive of Maoris, for whom no vital statistics are submitted either in this part or in the part on Maori hygiene, the mean population of New Zealand was 1,329,756, an increase of 31,121 on the previous year. The birth rate was 21.17

per 1,000, a steadily falling rate since 1916, when it was 25.94 per 1,000. The rate of stillbirths for every 1,000 live births was 30.6, a rate that has remained continuously high for several years. The infantile mortality, on the other hand, is extremely low, being only 39.36 per 1,000 births in the year under review, the lowest on record in the Dominion. The rate has steadily declined since 1900, when it was 75.2. Nearly half the deaths of infants—337 out of 744—were attributed to premature birth. New Zealand suffers from a high maternal mortality, deaths from puerperal causes being as high as 4.65 per 1,000 births in 1925, and still higher in previous years; but the relatively high mortality is due less to puerperal septicaemia than to other puerperal causes. The number of notifications of septicaemia, however, is high—11.93 per 1,000 births being returned as cases of puerperal fever. Although New Zealand compares unfavourably in this respect with some other countries, probably in no other country in the world is the death rate from all causes so low; for the crude rate in 1925 was only 8.99 per 1,000 of the mean population, and the standardized rate 8.67. It should be noted that stillbirths are excluded from both birth and death rates in the report, and no doubt the extraordinarily low infantile mortality is an important factor in the low general mortality rate. As might be expected in a population showing this remarkable state of health, no disease, either epidemic or endemic, has attained any prominence in the year under review, but both the Director-General and the director of the division of public hygiene have allowed an awkward error to creep into their reports in dealing with tuberculosis, for each refers to the incidence of this class of disease as gratifying or extraordinarily low, whereas in the tabulated statement the death rate from tuberculosis is shown as 5.14 per 1,000 of mean population. Obviously the decimal point should be placed differently or the rate recorded as per 10,000 of population, as in the tables of notifiable diseases. The Director-General in his survey refers to the increasing prevalence of cancer, but statistics of the incidence of this disease are omitted, so that no comparison can be made of its incidence in New Zealand as compared with other countries. Special features of an outstanding character in the report are the expansion and influence of the health department's maternal welfare services under Dr. Jellett, Dr. Paget, and Dr. Elaine Gurr, as also the excellent account of the division of school hygiene under the direction of Dr. Ada Paterson. An inquiry into the geographical distribution of goitre in school children and its relation to the amount of iodine in the soil was conducted by Dr. Baker-McLaglan, and is of much interest, as it demonstrated in a striking manner the relationship of goitre incidence to low iodine content. Many other public health activities are recorded, and it may be of interest to note that the number of registered medical practitioners in New Zealand is 1,211, or 1 to every 1,098 of population, exclusive of Maoris.

Among those recommended by the President and Council of the Royal Society for election to the Council at the anniversary meeting on St. Andrew's Day, November 30th, the following are members of the medical profession: Sir David Prain (treasurer), Dr. H. H. Dale (joint secretary), Sir Hugh Anderson, Sir Archibald Garrod, and Professor Robert Muir. The Royal Medals this year are awarded to two distinguished physiologists: Sir William Hardy, for his pioneer work on colloidal chemistry and the theory of lubrication; and Professor A. V. Hill, for his distinguished work on the physical and chemical aspects of muscular contraction. The Copley Medal is awarded to Sir Frederick Gowland Hopkins for his distinguished and fruitful work in biochemistry.

# RACIAL CHARACTERS OF SKIN IN RELATION TO HEALTH.\*

BY

H. J. FLEURE, D.Sc.,

PROFESSOR OF GEOGRAPHY AND ANTHROPOLOGY, UNIVERSITY COLLEGE OF WALES, ABERYSTWYTH.

PROFESSOR FLEURE said it seemed appropriate to devote the first Malcolm Morris Memorial Lecture to a consideration of the racial characters of the human skin and racial types in relation to health, because Malcolm Morris had been concerned in practice with the treatment of disorders of the skin, and also actively interested in hygiene—in the art of right living and the right use of environment, sunshine, fresh air, and cleanliness.

## Early Man and the Sahara.

While the poverty of body hair and the need for emitting heat are general features of mankind, differences exist between human groups in this respect and affect particularly the character of the skin, so that this has often been used as a basis for attempts to make a classification of mankind. The colour of the skin shows obvious differences in various regions of the world, and has been increasingly used as a basis of classification. Professors Leonard Hill and Ellsworth Huntington, from different approaches, have both reached the view that physiological efficiency is best maintained under cool temperate conditions with variability and storms as a feature. If we accept, broadly, the views of Hill and Huntington about bodily well-being and its weather conditions, we may argue thence that, at some stage before modern types of men had come to differ much among themselves, they were living in a fairly cool temperate, variable, and seasonally stormy climate. The earliest skeletal remains of men of modern type that we have were found in Europe, and belong to the days of the retreat of the ice sheets, after the last maximum phase of the Great Ice Age. It is reasonably certain that these men did not live in Europe during that maximum phase, and it is becoming ever more probable that they moved into Europe as climate began to improve. What are now the Sahara, Arabia, and Mesopotamia have, in the course of human history, changed from rather cool grasslands largely to deserts with long periods of great heat that dried their surfaces and led to pressure of their populations on the riverine belts of the Euphrates and the Nile and to drifting out of people in all directions. It is therefore more than likely that the early types of modern men had pigmented skins, the pigment being developed probably just after birth as the resultant reaction of the skin to influence of light in some way. Pigmentation is an almost universal reaction of skin to light. The rays of shorter wave-length—that is, the ultra-violet part of the spectrum—seem to be stopped in large measure by the horny layers of the skin; the rays of somewhat longer wave-lengths, but still towards the violet end, penetrate more deeply. They, like the ultra-violet, though to a less extent, have histolytic chemical influences. They are absorbed and converted into radiation of greater wave-length by pigment in the epidermis, and thus pigmentation may protect the dermis from deleterious effects of too much light. This gives a clue to the value of pigmentation, but, at the same time, we must not forget that the rays of short wave-lengths are invaluable in certain ways if in the right quantities.

## The Drift Southwards: the Dissipation of Body Heat.

Ape hair grows from roots deeply invaginated in the skin and the follicles have the form of fairly even lines at 50 to 80 degrees to the surface of the skin; the downy hair or lanugo, so abundant pre-natally in all human types, has roots of this kind and grows in similar fashion, and, in many races, the juvenile and adult hair grows quite similarly. It is thus probable that the skin of early modern men had hair of this type, and that other forms of hair, such as we now find among peoples of Mongolia, North China, etc., on the one hand, and among peoples of torrid

and South Africa, Papua, Melanesia, etc., on the other, are specializations. We are justified in arguing, both on grounds of general principles of climatology and on the grounds of Falconer's geological observations, that in the early days of modern man the African grasslands that are now the Sahara had a southern more or less desert fringe—an unfavourable environment for men at that stage. The early drifts southward in Africa were thus probable drifts of the less well equipped types, who were driven to face a climate that diminished their power of getting rid of body heat. They may be supposed to have been men with more than average pigment, though not very dark. The areas of very dark pigment in Africa are in some instances rather inhospitable, where poor food is characteristic and salt scarce.

Towards understanding the variations of colour in inter-tropical Africa, we may use the hypotheses:

- (a) That red and brown colouring are both fundamental, but that their relative proportions are liable to vary in different regions and among individuals, otherwise much alike, in one and the same region.
- (b) That regions with specially lowly societies, refugees of ancient types, societies on poor soil, apart from forest, tend to be specially dark.
- (c) That groups which have lived in the forest for generations are lighter than their relatives on open country. Forest regions of the north-east Congo appear to include groups that are almost olive.
- (d) The better lands usually have lighter coloured peoples.
- (e) There have been infiltrations from Algeria and Tibesti, and from people of the Nile, who have been red-brown from early times; infiltrations from that direction may have helped to produce the chocolate tint of the Berberines of Nubia, the Niam-Niam, peoples around Lake Rudolf, etc.

The shiny appearance of the skin, especially in Africa, due to sebaceous secretions from large and loose sweat glands with flabby pores, also promotes loss of heat. Yet another feature very widespread among the early drifts of men equatorwards appears to have been kinky, spirally curved hair arising from curved roots near the surface of the skin. These hairs do not appear much before birth. I associate this, and the extreme reduction of body hair that goes with it, with the need for getting rid of heat, this emission of heat being notably promoted by bringing the blood vessels nearer the surface. In some peoples, especially in Africa, the blood vessels are not only near the surface, but also highly developed, thus still further promoting cooling. It is not necessary to enlarge on further devices for cooling, such as the everted lips, the weakly developed nose, which lets air almost direct down to the pharynx, and so on.

Generally speaking, according to Dr. Shaxby's researches, the skin colour of intertropical peoples has brown and red constituents in varying proportions, the red being in part, but apparently not entirely, a blood effect. These brown and red constituents occur also in European skin, and it is impossible to get a line of demarcation between negro and white man as regards skin colour—every grade of intermediacy can be traced. The body skin of the forest pygmies of Africa often has a good deal of the downy hair of infancy on it, and a little is found among the head hairs of the Bushman, though he has little body hair. The forest pygmies are said to mature at 10 and to die of old age at about 40—a life-cycle of about the length found in apes—and their downy hair, their very feebly developed noses, their very prognathous mouths, their small stature, and other details all suggest that they are survivals from a far antiquity—that is, from very early variants of modern man, with very probably some degenerative features as well.

## The Drift Northwards.

As ice sheets diminished men were able to migrate not only to the south and east, but also to the north, and were presently pressed in this, as well as other directions, by the drying of the Sahara, etc. Some would spread across still-lingering land-bridges, such as that between Tunis and Sicily; others would spread into the grasslands of Turkestan and South Russia through the gaps between Elburz and Hindu Kush; others, probably, later would find Anatolia opening up ways into south-east Europe; and, finally, the ice sheets on the great central highlands of Asia would diminish sufficiently to allow such men as were inured to highland difficulties to enter them.

\* An abridgement of the first Malcolm Morris Memorial Lecture, given under The auspices of the Chadwick Trustees on November 15th, 1926, when Sir James Crichton-Browne, M.D., F.R.S., was in the chair.

With the passing of the ice sheets and the establishment of greenness and cloud in the European west, the evocation of pigment by glare during development became small, and this is a factor of the bleaching that in varying degrees characterizes the peoples of non-arctic Europe. A few individuals who still carry very ancient skull characters are found here and there in Tras-os-Montes, Sardinia, the Dordogne, the Welsh and Scottish moorlands, Norway, etc., and they are more swarthy than their neighbours: Where westerly winds rule in winter the blood vessels are often easily seen in the rather delicate skin, and we get the well known pink and white effect; but, in the regions of strongly marked winter anticyclones, such as the Alps and Carpathians and Poland, etc., a rather dead white is common. In a climate of fairly mild winters the blood vessels can safely lie fairly near the surface, and the coolness at the same time allows the superfluous heat, produced in the course of the active life appropriate to north-west Europe's climate, to be emitted easily. Exposure produces occasional local disorganization and consequent red blotching. With steadier winter severity seems to go a reduction of the superficial blood vessels. The relative hairiness that we have supposed to be a feature of early types of modern men is to a considerable extent maintained in European man, as we should expect in view of the general character of the skin, and the hair is typically wavy. The cool climate apparently prolongs the maturation phase, full maturity coming later than in most intertropical lands, but here social custom no doubt plays a part as well. The climate favours muscular activity, and this again helps to prolong growth and to delay full maturity; even some peoples of intertropical Africa who are very active hunters appear to mature relatively late.

#### North-east Asia.

The central highland of Asia, with its summer sun-glare and its winter snow-glare, and its very dry atmosphere, exposes the skin heavily to the action of ultra-violet rays, and brown pigment, probably fully ancestral, is general. We may look upon the North Chinese as, in a measure, depigmented, to some extent as we in Europe are depigmented. The north Chinaman is said to be darker in winter than in summer. In the types subject to the long cold winter anticyclone, whether they are brown or yellow, the skin is dry, sweat glands are scarce, and hair is scarce and coarse, the pores being firmly outlined and tightly filled. We note also the lack of heating quality in the normal diets of the region except on the high plateau, where, in winter at least, heat is obviously the great need. The dry cold Arctic atmosphere is very transparent to ultra-violet rays, and their reflection from the snow also gives them great power in this region. This doubtless accounts for the evocation of pigment. America received the basic elements of its population through north-east Asia, so it would seem that a large part at least of the native American stock is descended from persons with dry, rather hairless skin and brownish (red or yellow with the brown) colouring. This physical endowment has apparently undergone various modifications in different parts of the New World.

#### Europe.

In spite, however, of the favouring climate after the end of the Ice Age European peoples did not easily rise to their present position in the world, for they found special difficulty in acquiring the art of food production invented by the dwellers on the banks of the Euphrates and perhaps the Nile. Wheat and barley are almost certainly of south-west Asiatic origin, and it evidently took time before races of these plants suited to Europe were fully developed. Moreover, most of the European soils needed more management than those near the Euphrates, Nile, and Ganges, which were seasonally fertilized by silt from river floods, or those near inexhaustible stocks of loess in North China. Not only cultivable plants and domestic animals, but also a fairly high grade of social organization, had to be acclimated in Europe before our continent could make real headway, and there has generally been a tendency in our quadrant of the world to seek imported supplies of at least some materials.

#### Europeans in the Tropics.

The bodies of Europeans, and especially of the fair Europeans with blood vessels showing through the uncoloured skin, are engines adapted to ensure emission of a large amount of heat and consequent performance of a large amount of work. If we go to intertropical lands we suffer in many ways, two of which concern us here. The fair skin allows the actinic rays to penetrate it, and they set up a disturbance within, and the sensitiveness of the skin makes these and other intertropical sunlight effects the more dangerous. Besides this, the emission of heat is less easy under the equatorial sunshine, and an organism adjusted to a great heat loss is thus apt to get below par in a very warm climate. Therefore, whatever the effectiveness of our skin character in our own region, it is apt to bring about nervous debility, and is especially harmful to European children beyond the infancy phase—that is, in active childhood—in intertropical climates. This implies that, even with improved sanitation and extirpation of the causes of notorious diseases, the warm lands will still present grave difficulties to would-be European settlers, and especially to the fair Europeans. These are the more serious because European women living under the tropical sun are naturally very apt to struggle to maintain their fairness of skin—in other words, to resist adjustment to their adopted environment. The compromise of a sheltered life along with employment of coloured native field labour is now being tried out in various ways in several regions, but the attempt to maintain separate European and native groups side by side in the same place is full of social dangers, which react on health in myriad ways, and which are specially troublesome in view of tendencies towards some measure of nervous debility. Types which can be said to “pass for white” but have other blood in them at present seem likely to be more successful, and there are those who think that such elements will increase in some intertropical lands in place of the pure whites, and that these “pass for whites” will tend to diverge increasingly from the white standard and to emphasize the colour element in their inheritance as time goes on. Social conventions among many of the Protestant peoples of Europe, however, militate against any rapid multiplication of “pass for white” populations except among labourers.

From what has been said it will be seen that the fairest-skinned Europeans with their high power of heat emission and their activity of body and mind are more suited to rural than to town conditions, and the essential rural specialization of the Nordics in Europe has been a factor of our continent's history. Some very detailed observations by Mr. Bowen, now in progress, are tending to show that this kind of constitution is comparatively free from serious tuberculosis in agricultural areas, but that it becomes rather prone to this scourge when depressed into industrial poverty. Its vigour and activity in rural areas have led populations in which it is abundant to maintain a good level of feeding, though resistance to disease is often lowered by alcoholism, which seems in many cases to be an expression of the Nord's inability to find or to take advantage of a full outlet for his capacities of body and mind.

#### Town and Moorland.

We need much more observation, but it seems probable that the short, dark, long-headed man, who forms such a large element in the population of our moorlands and our big towns, can get through on the basis of less emission of heat, and he often has less physical energy and initiative. He more readily acquiesces in poor feeding in his moorland home, and there, especially in regions socially depressed by decay of mining or of farming, he seems very prone to tuberculosis. On the other hand, under industrial conditions in large towns where he can get food, of sorts, easily, tuberculosis appears to be less fatal to him than to the fairer types. Thus the character of the skin and hair, both among ourselves in Europe and among the various races of the world, seems to be in some degree an indicator of the general constitution, and especially of the mechanism of heat regulation. And these differences of constitution seem to connect themselves, not only with adaptability to certain climates, but also with resistance

to various diseases, of which I have taken tuberculosis as an example.

I venture to think that there is a future for the study of the incidence of various diseases and of the prevalence of various activities among people of diverse types, especially types of skin, but if that line be pursued the worker must clearly remember that environmental influences are at work all the time, and that, for example, our British dark long head on the moorlands may show features of strength and weakness different from those of the same type in the poor quarter of a large city.

## THE THEORY OF DIAGNOSIS.

DR. CROOKSHANK'S BRADSHAW LECTURE.

*The Bradshaw Lecture was delivered on November 4th, before the Royal College of Physicians of London, by Dr. F. G. CROOKSHANK. The lecturer, after paying tribute to the wit, humanity, and sagacity of Dr. Vivian Poore (who gave the first Bradshaw Lecture in 1881), said he had chosen as his theme the Theory of Diagnosis, since none other could be more proper to medicine, or to the branch of medicine called surgery. Indeed, even therapeutics must yield pride of place to diagnosis, for, in the words of Hart, written in 1625, "This part of Physicke doth farre excell the other, to wit the Therapeuticke, the which without the Diagnostieke is of small use and profit."*

Dr. Crookshank proceeded to justify the attempt to give an account of the theory of diagnosis—namely, to explain diagnosis by appeal to first principles that were independent of medical doctrine—by a discussion of the relations between science and philosophy. These had been ignored for the most part during the latter part of the nineteenth century, but were now receiving eager attention by those who saw, with Hobson, that natural science was a conceptual scheme and not a perceptual intuition, and who deplored the domination of science, until quite recently, by the philosophical theory of knowledge known as physical realism, still unconsciously sustained by those who proclaimed the freedom of science and medicine from the thrall of philosophy. If thought was to be clarified, in respect of this as of other subjects, it was necessary, as Galen said, to distinguish between words and things, and as Ogden and Richards had shown, to discriminate between words, thoughts, and things, thus following the injunctions of William of Occam, who, six hundred years ago, begged us to decide always in controversy and discussion whether a word was employed vocally: as expressing the intention of the mind; or representatively, for the object of thought.

The lecturer showed that the word "diagnosis" was generally employed in the Hippocratic Collection as indicating judgement, or cognition, and not as standing for discrimination between diseases, while Galen defined it as the "clear cognition of things present." It was not until the seventeenth century that the word appeared in the English language, and was then defined as meaning "dilucidation" or knowledge, while in the eighteenth century it was first used, in English and in French, as indicating the art of distinguishing between the diseases which the botanical physicians of that century, following Sydenham, defined and classified as if objects of perception, like plants or animals. It was only recently that an attempt had become obvious to restore the original usage of the word, and to realize that to "diagnose" in terms of diseases that were supposed to be entities was merely one method, or modality, of (in Dr. Christian's words) evaluating the signs and symptoms observed. Since the discard by medical men of general training in the theory of knowledge there had been, especially during the last hundred and fifty years, an increasing tendency to accept as of permanent validity and as corresponding to objects in nature, the conventions of diagnosis that had grown up, forgetting that, as Llewellys Barker had said, the groupings of signs of illness were conceptual, and to be changed when the purpose changed. Similarly, it had come to be believed that, in the process of diagnosis, physicians went through certain formal logical manoeuvres,

whereas psychological inquiry showed that, in diagnosing, some common faculty was exercised that satisfied both the intellectual and affective activities of the mind, "diagnosis" being just the name given to the first stage of the physician's work—the formation of those judgements arrived at by the interpretation of what was observed and expressed by the symbolization of the interpretations that guided him in his office of healing.

Thus considered, diagnosis appeared as a kind of reflex process which in a primitive, yet perfectly satisfactory, though purely selfish way, was exercised by the newt whose tail was cut off, and by the cat who sought the proper grass when ill, the "diagnosis" being in these cases symbolized by the growing of a new tail and the finding of the proper remedy respectively. It seemed possible that there might be ground for assuming the possession of some such instinctive power or ability by those "healers" who were able to express a diagnosis, for others, not in terms of orthodox convention, but therapeutically by manipulation or otherwise.

Discussion of the early philosophical trends amongst primitive man led to the conclusion that, at a very early stage in human progress, natural medicine showed tendencies for division into two schools, the one considering disease as a falling away; the other, as due to something added—a demon or the like. The same trends had been indicated throughout the whole history of medicine, those vitalists who regarded disease as a falling away belonging to the Coan school; the others, or organicists, who saw disease as something added or attacking, being in sympathy with the Cnidians and all who sought, in disease, the evidence of entities, whether diseases or demons. This division into two camps—evident enough even to-day—was only understood when the history of medicine was considered in relation to that of philosophy, the two medical camps corresponding closely to two philosophies—those of the sensualists, or empiricists, and of the Platonists, or rationalists. *Natural* diagnosticians, who diagnosed in terms of experience, corresponded to the sensualists, or empiricists; *conventional* diagnosticians, who diagnosed in terms of some rationalized type, were among the Platonists or rationalists. The former, in Mr. Trotter's phraseology, thought directly or concretely; the latter indirectly or abstractedly. The types, or universals, of the conventional diagnosticians were not objects of experience, but were mental constructs, justifiable only by their convenience and not as expressions of reality.

The lecturer proceeded to illustrate his thesis by reference to two stages in the history of medicine—the first marked by the controversy between the Coan and the Cnidian schools; the next by the struggle, in the sixteenth century, between the Hippocratists and Galenists of the Paris Faculty of Medicine. The Coan and Cnidian methods of diagnosis were shown to correspond, practically and philosophically, to the methods and thought of the natural and conventional diagnosticians of all time; and the gradual approximation of Galen, despite his admiration for Hippocrates, to a Platonic form of thought was insisted upon. It was by reason of the subordination of Galen's medicine to a Platonic philosophy that he became, in the sixteenth century, the titular head of those who, relying upon the tenets of scholastic realism, opposed the Hippocratic physicians who were, philosophically, nominalists.

It was in this way that the medical squabbles of the sixteenth century had, philosophically, the same grounds as had the opposition between Aristotelians and Platonists, and, in the Middle Ages, between the realists who upheld the extreme doctrine of the Real Presence and the nominalists who were accused with bitterness of undermining that doctrine. The medieval nominalists were to-day represented by the physicians who cared little for formal diagnosis in terms of clinical entities; and the realists by those who insisted on hard and fast distinctions between "entities" to which they allocated real, if not material, existence.

The influence of these modes of thought upon present-day problems was discussed, and the lecturer suggested that dissatisfaction with the diagnostic conventions of the last century was everywhere manifest, these conventions

being no longer adequate to their purpose—the proper storage and utilization of experiences, and knowledge. He suggested that a way of escape from the present difficulties, and from the apparent dilemma presented by the need for deciding between the two schools, might be found by attention to the method of thought known as conceptualism, first clearly put forward by William of Occam as a solution of the difficulties of the controversy between realists and nominalists, and, in these latter days, revived by such men of science and philosophers as Poincaré, Mach, and Vaihinger. Adoption of this conceptualism allowed escape from the illusions of realism and the limitations of nominalism alike, whilst permitting the freest use of helpful conceptions, or general notions, and liberty to observe, unhampered by an obstinate belief in the reality, or permanent validity of such notions as had already been propounded, in resumption of experience. In these circumstances the search for a correct diagnosis became rather a search for the best diagnosis possible—in the words of Hippocrates, that which enabled the physician to do what was right, and to constrain to his will, not only the patient, but the attendants and the circumstances.

Absolute diagnosis (said Dr. Crookshank, in conclusion) is a function of omniscience, and is exemplified only in the perfect restoration that it is the prerogative of omnipotence solely to ordain. It is not within our physical apprehension, and eludes us as does the absolute elude the physicist, the chemist, the mathematician, and the astronomer. But the idea of the absolute is necessary to every true science, and for the science of medicine is represented by the conception of the miracle of healing which, without verbalization, expresses, at one and the same time, the lesion of function and structure, and its effacement.

## MEDICAL MEN AND THE LAY PRESS.

### DISCUSSION AT HUNTERIAN SOCIETY.

A discussion on "Medicine and the Press" took place on November 15th, under the auspices of the Hunterian Society, at Cutlers' Hall, in the City of London. The chair was taken by Mr. MORRIMER WOOLF, president of the society, who said that the interest in this subject had become so acute that his council had thought it well to call a full and frank discussion in the hope of overcoming the misunderstandings which existed. He asked representatives of the newspaper press to bear in mind that so-called medical etiquette had been built up through many generations and had become a tradition which was cherished by medical men, not for their own advantage, but for the protection of the public.

LORD RIDDELL began by referring to the British Medical Association, and read in full the memorandum of the Ethical Committee approved by the Annual Representative Meeting last year. He said it was clear from this that any doctor who wrote for the press under his own name took his professional life in his hands. An inadvertent phrase, an extravagant headline, or an oily editorial comment might arouse the ire of the Association and land him in the clutches of the General Medical Council. It looked as if the General Medical Council reflected the policy of the British Medical Association, in view of the fact that the resolutions on advertising passed by the Council in 1905 and the amended Warning Notice of 1923 followed upon representations by the Association. He was himself a strong trade unionist, and the aims of the Association had his hearty sympathy—if he were a doctor he would be a member of it—but it should not be permitted to influence the policy of a body charged with the duty of exercising judicial functions, particularly when that body did not represent the whole profession. He thought also that the General Medical Council should report its policy, as displayed in its decisions on specific cases, in more precise terms. Again, to the onlooker it appeared that while the "big fish" in the profession could act with impunity, the smaller fry were caught in the net. He mentioned

as a form of advertisement for the most eminent members of the profession the signatures on bulletins regarding distinguished persons. He could not see why a doctor should be forbidden to write a newspaper article when he was allowed to publish the same matter without question in a five-shilling book. And apparently it was open to any medical man to advertise himself in the professional journals, not merely by the publication of papers, but by publishers' advertisements with extracts from reviews in praise of the authors. No one wanted a race of advertising doctors, but as an onlooker he could not help feeling that the British Medical Association took a somewhat narrow and prejudiced view. Let this matter alone, and a flood of signed articles on medical subjects in the lay press would soon kill the demand for them!

SIR HUMPHRY ROLLESTON said that in the widespread comment in the press on medical publicity there had been an undercurrent of suggestion that the profession was bound by some unreasoning etiquette or prejudice. While there was no serious contention that the profession was averse from health propaganda because the pockets of its members would suffer, there was an impression that it was obstructive. The well-being of the public as a whole was the commanding factor in determining the method of publication of medical matters in the lay press. Let it be agreed that some such public instruction in preventive medicine should be carried out. About the actual details of disease the public should be told little; the little that might be communicated should have reference to the initial symptoms of a serious condition, such as cancer, in order that persons so afflicted might be led to consult a doctor in the earliest stages. In general the less that healthy people knew about the details of disease the better for them. Information of every kind was, of course, available in books and professional journals, but there was a difference between what was intended for a professional audience and for an audience of possible patients. Medical men who signed articles in the lay press, however carefully and impersonally they wrote, were inevitably advertised, and thus directly or indirectly gained financially for a time, but not improbably estranged their more silent—perhaps more modest—brethren, whereby they were often eventually the losers. In the case of men not in practice and those in official whole-time appointments the objection did not hold. When, however, it was said that unsigned articles were poor "copy," the press seemed to forget that its own leading articles were unsigned, and their influence was not impaired. It seemed inconsistent that the press should have condemned Sir Thomas Horder's suggestion for an advisory board of medical authorities to guarantee the efficiency of writers of unsigned articles. In favour of the signed article by a well known physician or surgeon was his great authority and reputation, but where was the line to be drawn? And if everyone wrote, the door was open to self-glorification, the public would suffer, and the reputation of the profession would be lowered. The public also might easily be led astray by an honest enthusiast bringing forward a new and insufficiently tested cure for an old disease. Sir Humphry Rolleston objected to Lord Riddell's suggestion that the British Medical Association was a trade union. Certainly it had tried to protect medical men from being sweated by clubs and friendly societies, but the term "trade union" seemed to impute to it a course of conduct which elsewhere was responsible for industrial disturbance, if not war upon the community. Nor did he quite see the point of Lord Riddell's argument that the General Medical Council should have turned a deaf ear to the British Medical Association when that body made representations to it. The General Medical Council did not forbid the publication of articles or letters by medical men, but it had issued a Warning Notice against advertising for the purpose of procuring patients or promoting professional advantage, because this was contrary to the public interest and discreditable to the profession. An article which seemed to advertise the writer might bring a request to the writer to come before the Council and justify himself. The grounds on which a decision was reached in such cases, though clear to the Council, might not be so to the public.

and he noted that Sir Squire Spriggo had urged as a constructive measure that the Council should publish more details explaining the reasons for the decision in such cases. He added that the action of the Council was not influenced by the position of the alleged offender. In no case was a transgressor overlooked because he was a "bigwig," and he hoped that Lord Riddell did not really think that the Council was as snobbish as he had suggested. With regard to bulletins, the signature of these was very often in the nature of a command, and not at all on the initiative or at the wish of the doctors in attendance.

Mr. W. J. EVANS made some observations from the point of view of one who had been a working journalist. He asked what harm publication would do. He had read most of the articles of the New Health Society; they were most innocuous, there was nothing in them that he had not heard talked about at dinner-tables years ago. If newspapers liked to pay people for that kind of thing, well, it would mean a boom which would be followed by a slump. Leave the matter alone, and it would settle itself.

Dr. GRAHAM LITTLE, M.P., said that the feeling of responsible persons in the profession was, not that communications in the press were improper in themselves, but that the difficulties of contributing information worth giving were almost insuperable. It was not the communications so much as their intrinsic worthlessness that troubled the profession, which was made ridiculous by some of these contributions. He doubted whether the columns of a newspaper were the proper vehicle for medical exposition. He did not think the public would read serious contributions even if the newspapers accepted them; in the report of a medical lecture it was generally the frivolous passages that were picked out. The better plan would be to use the professional papers, the *British Medical Journal* and the *Lancet*, for the exposition of medical advice to the public. These journals were accessible, and might advantageously be made more so. It would be a good thing for the medical writer to be compelled to express himself simply and clearly, as he realized that his remarks might be read by the general public, and it would also be extremely valuable for the public to have the wise censorship of the trained staff of a professional journal. He thought the editorial committee suggested at the meeting of the St. Pancras Division a month ago would be too cumbrous. One of the dangers of indiscriminate publicity was the premature publication of unsubstantiated discoveries. It was unfortunate that the Medical Research Council, which ought to be a bulwark against such publications, had been in fact one of the worst offenders. He quoted two recent instances—the Dreyer vaccine, which was demonstrated to be a complete "wash-out," but had an immense burst of publicity in the lay press, and the extravagant claims made recently in the lay press in connexion with the admirable work on cancer by Dr. Gye and Mr. Barnard. He quoted the leading article in the *British Medical Journal* for November 13th as to the possibility of destruction under criticism of Dr. Gye's attractive theory. The Medical Research Council was placed in a difficult situation because it received large grants of public money, and its activities might be explained by the necessity of showing some results. In favourable comparison was the action taken by the British Medical Association through its Science Committee, which had done real service to the public by frank and careful criticism of some so-called discoveries much boosted in the lay press. In the case of the Spahlinger vaccine, for instance, it had been the means of preventing a good deal of public disappointment.

Mr. J. M. BULLOCK, speaking as a journalist, said that if a medical man wished to advertise himself no association would stop him. It was impossible to prevent newspapers from dealing with such an interesting subject as medicine, and so far as signed articles were concerned, the whole tendency of the press was now towards signature. The anonymous book review, for instance, was going out of existence. The real check upon abuse would come from the medical profession itself. He noticed that men who

were constantly writing even in the medical papers appeared to fall in the estimation of their fellow practitioners, no doubt justifiably so, because to court publicity needed an expenditure of so much time that the scientific work must suffer.

Dr. LEONARD WILLIAMS said that the public no less than the profession had got into a state of militant hysteria on this question. There never was or could be any such thing as a law prohibiting medical men from writing under their own name in the lay press. What the General Medical Council said was that if members of the medical profession felt they must write—it did not say that they should or should not—let them remember that they were gentlemen and members of a gentlemanly profession. Nevertheless, he had two objections to the Council's Warning Notice—one that it went into the motives of people who were supposed to be offenders, and the other that it was sent at the instance of anybody to the medical author of any article in the lay press. The author who received such a Warning Notice had a feeling that some responsible person thought he had done something he ought not to have done, which was not the case. If anybody imagined that writing for the lay press brought patients to the consulting room he was much mistaken. To preach a gospel of moderation and restraint in eating and drinking was by no means popular, and prospective patients would say, "If this is all he has to tell us, why should we pay three guineas to hear him say it?" The speaker had great respect for the British Medical Association on its scientific side, but very little on its ethical. It was not the only body, however, which acted as a "common informer" against members of the medical profession. The two defence societies also preferred claims against practitioners before the General Medical Council. After expressing his personal opinion of the Ethical Committee of the British Medical Association, Dr. Williams said that on the press itself there were gentlemen just as capable of judging whether a thing was desirable from the public point of view as was that committee. He held that it was the duty of those who could do so to educate the public in matters of simple personal hygiene; the present generation had grown up in ignorance of elementary laws of health, and the result was a C3 nation. Another unfortunate consequence was that by remaining silent the profession opened itself to the disgusting imputation that it did so in order that people might remain ill. If members of the profession were not satisfied with things as they were there was a ready method of altering them. Those who governed the British Medical Association and the defence societies were elected persons; turn them out!

Dr. T. B. HYSLOP said that he belonged to the class of mental specialists who were never called upon to sign a public bulletin, and whom no patient ever acknowledged having consulted. Nevertheless, the press sought for their opinions with some persistency. He gave an amusing instance of how a frivolous remark of his about the multitude of diseases from which "Rima" appeared to be suffering brought him innumerable press inquiries, with his photograph in the newspaper, until he had in sheer self-protection to announce that he only gave an opinion on a patient when the patient was brought to him with an accrediting letter from a medical man, and that only to the medical man was the opinion given. Dr. Hyslop believed that this whole question would find its level. Certain it was that those who advertised went down in the estimation of their medical brethren. Even from the point of view of the papers, would it be wise to have much authentic medical information? How would it affect the yards of advertisement of remedies for uric acid, premature baldness, and ingrowing toe-nail? He felt that the time had come to lay down their arms and call a truce. This subject was being thrashed out *ad nauseam*.

Lord RIDDELL briefly replied, and Sir SQUIRE SPRIGGO and Dr. HALLS DALLY spoke to a vote of thanks.

## THE SCHOOL OF HYGIENE AND PUBLIC HEALTH OF THE JOHNS HOPKINS UNIVERSITY, BALTIMORE, U.S.A.

IN the BRITISH MEDICAL JOURNAL of July 10th (p. 75) an account was given of the new building planned to accommodate the London School of Hygiene and Tropical Medicine, which, it will be remembered, was rendered possible by a grant from the Rockefeller Foundation. Similar generosity on the part of this Foundation enabled the School of Hygiene and Public Health at Baltimore to be housed in an edifice worthy of its important work, and the following article describes the building in detail, here and there instituting a comparison between the arrangements made at Baltimore and in London. Save incidentally, it does not refer to the courses of study now given at the Johns Hopkins Hospital. For details regarding the curriculum the reader is referred to the Johns Hopkins University Circular, the catalogue and announcement of the School of Hygiene and Public Health, 1926-27, to the *American Journal of Hygiene* for September, 1926, which contains an excellent illustrated monograph on the school, or to a review of that monograph which will appear shortly in the *Bulletin of Hygiene*, one of the publications of the Bureau of Hygiene and Tropical Diseases.

The new building of the School of Hygiene and Public Health was officially opened on October 22nd, 1926, at the time of the celebrations commemorating the fiftieth anniversary of the Johns Hopkins University. The school itself, however, came into being in the autumn of 1918, and was at first supported by an annual subscription of 250,000 dollars from the Rockefeller Foundation. In February, 1922, the Foundation converted this grant into an endowment fund of 5,000,000 dollars, given to Johns Hopkins University, and made a further appropriation of 1,000,000 dollars for the construction of a suitable building for the purpose of the school. For seven years after its foundation the school occupied temporary quarters in laboratories used by Johns Hopkins University before the university moved out to Homewood, its new and magnificent home on the outskirts of Baltimore. Although plans for the new school building were prepared in the spring of 1912 by the architects, Messrs. Archer and Allen of Baltimore, in consultation with Messrs. Coolidge of Boston and Turner of New York, circumstances conspired to delay its erection, and it was not ready for occupation until the autumn of 1925. Since that date, however, work has been actively prosecuted in it.

The ceremony commemorating the opening was arranged to form part of the celebrations in connexion with the fiftieth anniversary of Johns Hopkins University, to which numerous guests from various parts of the United States, Canada, and also from overseas, had been invited. From Great Britain there were present Dr. Andrew Balfour, director of the London School of Hygiene and Tropical Medicine, and Professor R. T. Leiper, director of the Department of Helminthology in that school and also of the Institute of Agricultural Parasitology. To Dr. Balfour had been entrusted the delivery of the address: he chose as his subject "Hygiene as a world force," and the lecture, in an abridged version, was published in the *BRITISH MEDICAL JOURNAL* for October 30th.

The scene at the Lyric Theatre on October 22nd was brilliant, the body of the hall and the galleries being filled with an audience of about two thousand people. To the strains of a string orchestra the academic procession, headed by Dr. Goodnow, president of the university, and Dr. Balfour as principal speaker, entered the auditorium and proceeded to the platform. The varied hues of the different gowns and hoods representing Hopkins, Harvard, and other American universities, Paris, Oxford, Cambridge, several Scottish universities, and a number of Continental schools, supplied vivid splashes of colour in the seats reserved in the body of the hall, and upon the platform. A notable figure was that of Professor L. Lévy-Bruhl of the Sorbonne in the fine uniform of the Knights of Pythias.

The proceedings opened with an invocation by the Right Rev. John Gardner Murray, Bishop of Baltimore. In the unavoidable absence of the Governor of Maryland, an address of welcome was delivered by Adjutant-General Milton A. Reckford. He was followed by Dr. William H. Welch, the "good gray doctor," as one of the newspapers called him, who, despite his years, easily made himself heard in every part of the huge building. He told how the

school came into being, spoke of the 278 men and women who had been trained there in the principles of preventive medicine, acknowledged the debt of the school to the Rockefeller Foundation, and welcomed Dr. Vincent, its president. After paying a fine tribute to Dr. W. H. Howell, assistant director of the school and professor of physiological hygiene, Dr. Welch introduced Dr. Balfour, upon whom Dr. Goodnow conferred the honorary degree of Doctor of Laws of Johns Hopkins University. Dr. Balfour, after briefly returning thanks for the honour done him and the school he represented, delivered his address. In the afternoon the School of Hygiene and Public Health was open for inspection, and large numbers of visitors were conducted round it by Dr. Welch and members of his staff, after Dr. Welch had delivered an address explaining the objects and work of the institution. Later the Do Lamar lecture was given by Professor F. Neufeld, director of the Institute for Infectious

SCHOOL OF HYGIENE, JOHNS HOPKINS UNIVERSITY.

Diseases, Berlin, his subject being "Variability of bacteria, with special reference to infectious diseases."

This concluded the proceedings so far as the commemorative exercises for the opening of the School of Hygiene and Public Health were concerned.

The school is not a department of medicine, but a separate entity with an independent faculty, co-ordinate with the other faculties of the university. This faculty consists of 13 full professors, 7 associate professors, 9 associates, 3 instructors, 12 assistants, and 5 extra-mural lecturers. The director is Dr. William H. Welch, so well known for his activities in many fields, a man of world-wide reputation, and as renowned for his genial and inspiring personality as for his scientific and literary attainments. The school contains the following departments: public health administration, epidemiology, biometry and vital statistics, sanitary engineering, bacteriology, immunology, medical zoology including protozoology, helminthology, entomology and filterable viruses, physiological hygiene and chemical hygiene. This arrangement differs from that adopted for the London school in a few particulars. At the latter epidemiology will be combined with vital statistics to form one of the six divisions of the school. Similarly, bacteriology

and immunology will be united. At London there will be no separate division or department of sanitary engineering, although a laboratory is earmarked for the study of that important subject. The division of medical biology in the London school will contain a department of comparative pathology, and no arrangements have been made for a department of filterable viruses, the study of which will be carried out in the division of bacteriology and immunology. In other directions there is a close approximation between the two schools, but the fact that the London school is not only a school of hygiene but a school of tropical medicine has necessitated provision for the teaching of that subject, notably in the form of a laboratory for the study of tropical hygiene and pathology. Another difference is the large amount of space devoted to the museum in the London school—a museum intended to give a graphic representation of everything pertaining both to hygiene and tropical medicine. At present the school at Baltimore does not possess a museum, and the space allotted for museum purposes is comparatively small.

Turning now to a description of the new building in which the Johns Hopkins school is adequately and fittingly housed, it will be seen from the accompanying photograph that this new home of hygiene is of an impressive and dignified character. Unlike the London school, it is built upon an island site, and, in accordance with American tradition, it soars heavenward, having eight full stories above the basement, together with some additional rooms on the ninth floor.

The London school is H-shaped, the Baltimore school takes the shape of the letter E. The building is located at the corner of Monument and Wolfe Streets in East Baltimore, and is in close proximity both to the Johns Hopkins Medical School and the Johns Hopkins Hospital. It forms part of the medical centre which has been developed under the joint auspices of the university and the hospital. It houses all the work of the School of Hygiene and Public Health, except that in sanitary engineering, which at present is conducted in the engineering laboratories of the university at Homewood. The front of the building, adorned by a fine portico, faces west, and is 180 feet long. The main building has a width of 51 ft. 4 in. Three wings project to the east, forming the arms of the E. The central wing is 35 ft. 6 in. in length by 51 ft. 4 in. in breadth. The other two wings are 27 ft. by 37 ft. 6 in. The construction is of steel and hollow tile, with a facing of light-coloured brick, save in the case of the lower three stories and the eighth story, which are finished in limestone. The general effect is distinctly pleasing, and the brick and limestone harmonize admirably. The treatment of the large windows of the eighth story and of the cornice adds to the distinction of this notable pile. At the back there is a separate one-story structure which serves as a stable for large experimental animals, houses an incinerator, and provides storage for chemicals of an explosive nature.

(To be continued.)

## England and Wales.

### CONSULTANTS FOR LONDON MENTAL HOSPITALS.

The Mental Hospitals Committee of the London County Council has been considering the desirability of securing the affiliation of the mental hospitals to the general hospitals, and in the first instance, to facilitate the attainment of the object in view, it proposes to appoint certain consultants to the mental hospitals, leaving further arrangements to develop as may be found advantageous to the two classes of institution concerned. A consulting physician, surgeon, gynaecologist, ophthalmologist, and throat, nose, and ear surgeon are to be appointed, and as a first step arrangements have been made for consultants from London and Guy's Hospitals to attend the Claybury and Bexley Mental Hospitals at a fee in each case of £4 14s., inclusive of travelling expenses. During the first year of this arrangement the expenditure will be limited to £400, which will permit of forty-two visits being made at each hospital during the period.

### TREATMENT OF DIPHTHERIA CARRIERS.

At Guy's Hospital a special clinic has recently been opened, as an experiment for one year, for the treatment of children who are found in the course of medical inspection to be carriers of diphtheria germs, though otherwise in normal health. Such cases are not suitable for admission to the Metropolitan Asylums Board's fever hospitals, and there have been no facilities for their proper treatment at the general hospitals or school treatment centres. Twelve school children have already attended the Guy's clinic, which is open on one afternoon of each week. The London County Council has agreed to defray the travelling expenses of parents who take their children to such a clinic.

### HOSPITAL EXTENSION AT WESTON-SUPER-MARE.

A memorial to the late Queen Alexandra at Weston-super-Mare is to be erected in the form of an extension to the hospital, which was originally founded as a dispensary in 1857 and modified in 1865; the foundation stones were laid on November 11th. The new buildings consist of two ward blocks of two floors each; four main wards are provided, each containing fourteen beds. Wide verandahs will surround the ward blocks on three sides, and be capable of taking all the beds from a ward. Between the ward blocks is a central building comprising an entrance hall, a waiting room, and casualty and out-patients' departments, with a complete theatre unit on the first floor. The existing buildings are being extensively reconstructed and modernized and a new wing will be added, so that a complete new department for radiology and electro-therapeutics may be obtained. Rearrangement of two wards on the first floor will enable a number of private single beds to be installed, and accommodation is to be provided for two resident medical officers. Another building, originally intended as an isolation block, and at present used as an x-ray department, is to be converted into a maternity block, with beds for pre-natal and post-natal treatment as well as a small labour ward.

### DESTRUCTION OF VERMIN.

An institution known as the College of Pestology (Incorporated), and formed to encourage vermin destruction on scientific lines and to make known the havoc wrought by insect and other pests, held its annual dinner at the Hotel Cecil on November 11th, when Sir William Bull, M.P., occupied the chair. Among the company were Sir John Lynn-Thomas, Dr. R. A. Lyster, Dr. Clark Trotter, and other medical men. The chairman said that a recent enlargement of the council of the College had enabled various panels to be formed, one of which was devoted to field entomology, another to house hygiene, and a third to medical economics, the purpose of this last being to study and make known the wastage of human life caused by insects. He expressed the hope that the time might shortly come when this institution would be a constituent college of the University of London. It was hoped to make rat week next year an occasion more successful than previous efforts of the kind, and to that end it was intended to invite the co-operation of leading medical officers of health throughout the kingdom, also the heads of large businesses, in formulating measures which it was hoped would meet with the approval of the Ministries of Health and Agriculture. The chairman of the college, Mr. A. Moore Hogarth, in expressing acknowledgements to the press for the help it had given in making known the proper measures for the destruction of pests, remarked that not even fratricidal warfare, with modern engines of destruction, created such a shambles as did insect and other pests driven by the fight for existence to make war upon man. Other speakers were the Hon. Cuthbert James, M.P., President of the College, who urged every medical officer of health to equip himself with the classic work on the subject of the rat and its destruction, by Mark Hovell; and Mr. F. T. G. Hobday, who referred to the importance of the study of pestology to those engaged in veterinary work. Mr. Hobday instanced, among other matters, the havoc wrought by the little gadfly on the hides of cattle, to the detriment of the future leather, also the part played by the rat in the spread of foot-and-mouth disease. During

the evening the annual gold medal in honour of one of the founders of the college, the late Professor Maxwell-Lefroy, was presented by his widow to Mr. G. F. J. Toll, sanitary inspector, Bermondsey, for an essay on the bed-bug (*Cimex lectularius*). Next year's award will be for the best monograph on the house-fly.

#### DAIRY RESEARCH AT READING.

The National Institute for Research in Dairying is one of those curiously disguised modern institutions in which the State pays a large part of the cost of the piper, while the appearance of voluntarism in the tune is kept up by subscription. This is called the pound for pound principle; but the voluntary pounds are often in arrears. The institute was established in 1912, and is now a part of the University of Reading, and possesses a farm, a dairy, and laboratories at Sheffield; it was part of a scheme by which the field of research was divided up by subjects, each subject being dealt with at a particular centre, usually in conjunction with a university. The difficulties encountered at the Reading Institute in extracting money by public appeal have been tided over by the generosity of Lord Elveden. There can be little doubt that the institute is well worthy of support by the producer and by the consumer, both of whom benefit by the researches that are carried out in its three sections—dairy husbandry, chemistry, and bacteriology. Many of the experiments have been conducted in old farm buildings, so that the advice given to farmers was based on research work under ordinary conditions, without the advantages of convenient, easily cleaned, and well lighted buildings. From the reports of the institute the farmer may learn that hay containing *Anthraxis cotula* (stinking mayweed) will taint the taste of milk. Marrow stem kale and tomato-seed cake will have the same effect when used as food in excessive amounts. "Ropiness" in milk has been shown to be due to two entirely different causes: there is a physical variety due to the formation of thin films of casein or lacto-albumin as the milk passes over the cooler, and there is a more common type in which milk in bulk becomes "ropy" from the growth of bacteria. Reports have also been issued by the institute on variations in the live weight of dairy cows, and experiments have been made on the yellow discoloration of Stilton cheese. From the medical point of view the discovery that liberal supplements of cod-liver oil in the winter food of stall-fed cows decreased the percentage of fat in the milk is of interest; so, too, is the proposal to use dried whey as human food. This product has already been shown to be a very valuable food for pigs. It is not stated whether a similar extension of consumption is proposed for dried whale-meat meal, another valuable pig food. The bacteriologist will be interested to learn that the "mechanical surface aggregates" in ropy milk are of importance in handling dilutions of milk in the course of bacterial enumeration.

## Scotland.

#### PUBLIC HEALTH WORK IN EDINBURGH.

Dr. WILLIAM ROBERTSON, medical officer of health for Edinburgh, in a lecture delivered on November 12th, asked whether preventive medicine was making progress commensurate with the great outlays now being made. In returning an affirmative answer, he instanced the facts that the expectation of life had been prolonged, that infantile mortality had been lessened, that tuberculosis was slowly declining, and that the control of infectious disease was within our grasp. The annual expenditure on public health in Edinburgh in 1910 had been about £35,000 and in 1921 had reached £120,000, though it now stood at little over £100,000. Better housing, saner feeding, and greater facilities for recreation had done much to fortify the individual against attack from infectious diseases. Scarlet fever was not now so severe as it used to be, and diphtheria was less malignant. New weapons for combating diphtheria had been placed at their command, and Edinburgh had taken a lead in fighting this

disease. In dealing with measles and whooping-cough, the lead given by Edinburgh was now being followed elsewhere, and children suffering from these diseases were being to a greater extent admitted to hospital. This had been rendered possible by the treatment of mild cases of scarlet fever in the patients' own homes. By shortening the stay of scarlet fever cases in hospital also, through recognition of the fact that the peeling skin of scarlet fever patients was not a source of infection, a saving of £3,000 had been effected in hospital treatment in one year. Tuberculosis, which had caused 30 deaths per 10,000 of the population in 1856, now caused 10 per 10,000, and this reduction had been largely due to demolition of slums and the admission of sunlight and air into the houses. Housing schemes, though slow, were making great changes, but it would be necessary to build 1,000 houses a year in Edinburgh for the next ten years.

#### GLASGOW "HEALTH BULLETIN."

The *Health Bulletin*, issued by the medical officer of health for Glasgow, for August, September, and October, 1926, shows that the prevalence of scarlet fever in the city has continued; the highest number of notifications was 163 in the week ended October 2nd. The disease in general has been mild, the case mortality being 0.8 per cent. The period of detention in hospital has accordingly been reduced, without untoward results. Treatment by antitoxin in severe attacks has lessened severity and shortened duration. One case of typhus fever has to be added to the seven reported in the previous issue of the *Bulletin*, making a total of eight cases. In all the cases the Weil-Felix reaction was positive. In one case the rash was extensive and haemorrhagic, while the constitutional disturbance was comparatively slight. There was one death among the older group of patients. Direct contacts in all instances were kept in a reception house under observation. Enteric fever was represented by 53 cases, of whom 29 reacted to *B. typhosus*, 1 to *B. paratyphosus* A, and 23 to *B. paratyphosus* B. The paratyphoid A case was infected in France. From several cases of illness presenting symptoms suggestive of food infection Flexner organisms were recovered.

#### CENTRAL MIDWIVES BOARD FOR SCOTLAND.

The examination of the Board, held simultaneously in Edinburgh, Glasgow, Dundee, and Aberdeen, has just concluded. Out of 101 candidates 86 passed; of the successful candidates, 15 were trained at the Royal Maternity Hospital, Edinburgh, 22 at the Royal Maternity Hospital, Glasgow, 5 at the Maternity Hospital, Aberdeen, 6 at the Maternity Hospital, Dundee, 4 at the Queen Victoria Jubilee Institution, Edinburgh, and the remainder at various recognized institutions. At a special meeting of the Central Midwives Board for Scotland for the hearing of penal cases, Dr. James Haig Ferguson in the chair, a report in regard to the practice of a certified midwife was submitted. In accordance with the decision of the Board, intimated at a previous meeting, the report being unfavourable, her name was *ipso facto* removed from the Roll, and the secretary was instructed to cancel her certificate.

#### NEW INFIRMARY AT FALKIRK.

The ceremony of cutting the first sod for the new infirmary for Falkirk and district was performed on November 10th by the Duchess of Montrose. The Duke of Montrose, in addressing the meeting, said that he and the Duchess were pleased to take part in this ceremony, because both their families—that of Hamilton and that of Graham—had been bound up with the affairs of Falkirk for hundreds of years. It was a curious fact that, while statistics showed the health of the country to be improving day by day, the need for infirmaries grew more and more. Some years ago Falkirk had had a hospital with 14 beds, then an infirmary with 70 beds, and now a new institution with 130 beds was required. This was due partly to the growing confidence of people in hospitals and partly also owing to the development of transport. Infirmaries were maintained very largely for the free treatment of the very poor. In America a large part of the income of hospitals

was derived from paying patients, and it would be to the advantage of infirmaries in this country to provide for paying patients as well as to give free treatment. This would be a suitable source of income, and in the end would enable the hospital to provide the best of medicine, surgery, and nursing for all those whom it served. The site of the new infirmary includes ground extending to 12 acres round the mansion house of Gartcows; the administrative, admission, and out-patient departments about on the public street, while the wards will be placed on the more retired portions of the ground. The administrative buildings, and also a building to afford accommodation for 130 beds (with an ultimate capacity of 250), are to be erected at once. Various annexes for eye, ear, nose, and throat clinics and for artificial sunlight and electrical treatment are also being erected, and accommodation for private patients and the provision of a maternity department are contemplated.

#### HOSPITALS AND MOTOR ACCIDENTS.

Following upon action taken by the managers of the Royal Infirmary at Edinburgh in regard to the treatment of motor accident cases in that institution, as mentioned in the *BRITISH MEDICAL JOURNAL* for October 30th, p. 807, Mr. J. Scott Riddell, C.M., LL.D., chairman of Aberdeen Royal Infirmary directors, drew attention at a meeting of directors on November 10th to the increasing number of patients suffering from motor accidents and the effect on the waiting lists. During the present year 92 motor accident cases had been admitted, involving a total inpatient stay of 2,449 days. The annual maintenance cost of these was about £650. The effect on the waiting list had been to keep out 120 extra surgical patients who otherwise would have passed through the wards during these ten months. It was suggested that the Aberdeen Royal Infirmary should ask insurance companies to accept responsibility for these accident cases. It was also mentioned that the erection of new accident wards for 30 beds was being pushed forward, that they would soon be ready for occupation, and would relieve the congestion.

## Ireland.

#### MEDICINE FROM THREE ANGLES.

DR. E. T. FREEMAN delivered the inaugural address at the opening meeting of the session 1926-27 of the Medical Society of University College, Dublin. The address was entitled "Medicine from three angles," and in the course of it he said that before considering how the recent advances in medicine affected either the practitioner, the student, or the man in the street, it was necessary to remember the character of the times in which they were living. They had lately passed through the greatest war in history, and were in an age of rapid transport and of quick dissemination of ideas. They had come to the end of a period of universal exaltation, and were sunk in universal disillusionment. They were at the mercy of the mass-producer, of the newspaper with the greatest circulation, of the publicity agent and the advertising expert. As medical knowledge increased and as the methods of investigation and treatment became more and more complex, it was gradually realized that no man could possibly have a complete knowledge of the whole. The result of this was specialization, and the dangers of specialization appeared to be a series of water-tight compartments on the one hand and the group system on the other. It was but a short step in this evolution from the private group, which was mass production, to the group controlled and paid by a public company. This was mass production with the aid of the modern business prospectus, advertising expert, and newspaper proprietor. This scheme had appeared in the United States. It meant the entrance into medical service of corporations dispensing diagnosis and treatment on a wholesale basis, employing groups of physicians for the purpose, remunerating them, and paying away the surplus in the form of dividends. This completely removed the personal element. If companies were open to the charge of being soulless as employers, they would hardly be less so

as doctors. A generation ago the chemist compounded medicines prescribed by the physician; now in many cases he merely provided the mixture, the compound, or the tablet put up by the manufacturer, and ordered as such by the practitioner. This result had followed the enormous growth of the commercial laboratory and its incorporation in the drug-manufacturing houses. It had had many advantages; many most valuable drugs had been introduced; preparations were now more accurately measured; drugs were of a higher standard of purity and activity; they were dispensed more attractively, and were standardized. Nevertheless, there was the danger that prescribing might be taken out of their hands without their realizing what was happening. At the present time there was a boom in endocrine and similar products. Many of these had neither physiological nor clinical reasons for being employed. Many, indeed, were not glandular products at all. A great number were inert. They were prescribed by some doctors because they had not the means to appraise their value, by others because their resistance had been broken by too formidable a bombardment of advertisements, by the rest because they had not read *Martin Arrowsmith*. The privately owned or controlled periodical was a latent source of danger, as was also the indiscriminate multiplication of semi-professional journals devoted to popular aspects of therapeutics, but really kept going by the makers and vendors of the apparatus advertised in them. How this evolution of medical practice affected the public could conveniently be considered under two heads—the first dealing with the direct effect of changing practice, and the second with the attitude of the public towards medical problems generally. As medical processes became more involved, and as scientific apparatus became more costly in purchase and maintenance, treatment and examination necessarily became more expensive. It had also become generally realized that nursing was a difficult and technical business which could not as a matter of course be safely entrusted to any one of the patient's friends, and that the patient's home was usually the worst place in which to treat any ailment other than the simplest. The recognition of these facts had brought about a great change in the personnel of hospital patients. The attitude of the public towards medical matters deserved the very close consideration of every medical practitioner. The public was at present vitally interested in medical topics. It followed with interest reports in the popular press of new discoveries and new treatments. It was disposed to find orthodox medicine too slow, and to seek short cuts in osteopathy, Couéism, and the like. The vexed and now prominent question of medical practitioners contributing articles to the public press was closely related to this point. It was quite obvious that the public was in need of instruction and enlightenment, and some contended that the signed article in the popular press was the best means of meeting this need. This was an innovation, wholly opposed to the rule of their profession against the advertisement, direct or indirect, a rule made and kept in the best interests of the public itself. Articles by medical men in practice might well contain views that were personal and in conflict with the opinions of the profession as a whole. The public was not fit to judge between opinions, and the medical press was clearly the proper place for such publications. The issuing of instructions and information from medical officers of health or from the medical officers of a Ministry of Health who were not in practice was, on the contrary, a very desirable thing. But the public did not want enlightenment; it wanted interesting paragraphs; hence the regular appearance in certain newspapers of medical material written up by popular journalists. A careful watch on these paragraphs showed that subjects of momentary topical interest very largely predominated. Dr. Freeman concluded, therefore, that the public needed to be saved from its own carelessness and indolence, and protected from cranks and cultists; and that it very badly needed instruction was well demonstrated by the recent history of small-pox.

#### TUBERCULOSIS IN BELFAST.

Reporting on the work during 1925 of the tuberculosis department of the county borough of Belfast, Dr. Andrew Trimble, the chief tuberculosis officer, states that there

has been a reduction of the death rate due to pulmonary tuberculosis in Belfast of 30 per cent. in the last ten years, 55 per cent. in the last twenty years, and 60 per cent. in the last thirty years. He refers to the question of the effects of tuberculosis on pregnancy, and concludes that the disease cannot be convicted of contributing in any marked degree to interruption of the normal course of pregnancy. He finds that if a tuberculous woman is not in an advanced stage of the disease, or acutely ill, is well nourished and lives in hygienic surroundings, pregnancy and child-bearing have little apparent effect on the clinical course. On the other hand, in advanced stages of the disease, or when the patient has an acute type of tuberculosis, pregnancy may be attended with very serious results. He emphasizes the value of *x* rays in the diagnosis and prognosis of pulmonary and osseous tuberculosis. He has frequently found that, even when a sinus has appeared to be firmly healed for many months, or even years, the *x*-ray film may still show much rarefaction of the diseased bone, indicating the need for further rest and treatment. With regard to the diagnostic importance of the albumin test in sputum, he states that out of 850 examinations for albumin or albumose, only 14 were found to contain tubercle bacilli and no albumin, while 127 which contained tubercle bacilli gave also a positive test for albumin. He adds that even if a negative albumin reaction is of uncertain value as indicating the absence of pulmonary tuberculosis, a positive reaction is an indication for the repeated examination of the sputum for tubercle bacilli. Dr. Trimble gives a short account of the visit of the medical commission from Belfast last year to Paris, Geneva, Frankfurt, Hamburg, and Copenhagen to investigate Continental methods of treating tuberculosis. He also gives a report on the work of the Belfast committee which has been investigating the value of sanocrysin, and concludes that, while the method seems to represent a distinct therapeutical advance in definitely selected cases, further observation of the results for at least a year will be necessary in order to estimate the degree of permanence.

## Correspondence.

### OPERATIVE TREATMENT OF PYLORIC STENOSIS.

SIR,—I was rather hoping that someone more competent than I would remark on the two cases reported in your issue of November 6th (p. 835). I do not think that your readers should be left with the idea that pyloroplasty or gastro-enterostomy are nowadays operations worthy of even a passing thought for these cases.

The matter was reviewed in an article published in the *Annals of Surgery* in August, 1911 (p. 167), in which the pioneer work of Dr. Cautley and Mr. Clinton Dent was considered. Gastro-enterostomy was shown to have a mortality of 42 per cent., division of 50 per cent., and pyloroplasty of 27 per cent. The difficulties of pyloroplasty were discussed in this paper, and attention was drawn to the fact that "Cautley and Dent have pointed out—indeed, almost complained"—that there is plenty of mucous membrane. Further—and I look upon this as of the greatest importance—it was in this article advised to divide the pyloric ring "in a longitudinal direction down to, but not including, the mucous membrane. This was, I believe, the first time that the suggestion of not dividing the mucous membrane had been made, and the operation as suggested in this paper was carried out with success both in England and also, to my knowledge, in Australia.

Rammstedt, a little later on, effected a further saving of time by leaving the divided pyloric sphincter and peritoneum without any attempt at closure; he retained the essential feature of the operation above referred to, and neither divided the mucous membrane nor took the time required to sew it up again.

I notice your correspondent states that he considered it useless to perform Rammstedt's operation since the pylorus would "admit nothing more than a large probe." Surely this remark implies a failure to realize the essence of the operation advised in the article above referred to and adopted by Rammstedt—namely, that the mucous mem-

brane should not be divided. Your correspondent must have divided it before examining the pylorus with a probe. It also implies a want of knowledge of the work of Cautley and Dent, who "almost complained" of the redundancy of the mucous membrane. It is the hypertrophied muscle which causes the narrowing, and this is at once relieved by its division.

For further information I should like to refer your readers to the various papers which Mr. Tyrrell Gray has published on this subject.—I am, etc.,

Exeter, Nov. 14th.

RUSSELL COOMBE.

P.S.—I understand that in competent hands the present mortality of Rammstedt's operation for cases operated on within four weeks of the onset of symptoms is in the neighbourhood of 8 per cent.

### EPIDEMIC ORCHITIS AND MASTITIS.

SIR,—During this autumn the catarrhal epidemic started earlier than usual—namely, in the beginning of October. Up to the present the complications have not been severe. The cases of so-called "gastric 'flu'" have been many, with an acute onset of pain in the abdomen, accompanied by perhaps vomiting or diarrhoea, according to the site of infection. Some of the severer cases have been followed by jaundice or colitis.

One feature of the epidemic, however, which is rare is the complication of orchitis or mastitis.

In severe cases of influenza orchitis is not unknown, but is usually overshadowed by the severity of the disease itself. During this epidemic the cases of orchitis have not presented any severe influenzal symptoms, but have reported on account of the testicular condition itself.

Within the last fortnight I have had five cases of orchitis and three of mastitis, all uncomplicated by any other disease. The orchitis has not been very acute, and in no case have the parotid or any other glands been involved. There is a slight rise of temperature for twenty-four hours, and the condition has subsided within a few days. The cases of mastitis have followed very much the same course, and have been in no way connected with any generative condition. I have had no case of ovaritis.—I am, etc.,

Streathley, Berks, Nov. 10th.

LEONARD LESLIE, M.D.

### MEDICAL PRIVILEGE IN THE COURTS.

SIR,—Dr. W. E. Levinson, in your issue of November 13th (p. 908), asks if he was right in not reporting to the police that a patient to whom he had been called had been stabbed by her husband. He was quite right, and Mr. Justice Swift was quite unjustified in his hasty censure. If it were supposed to be at all likely that a doctor would in such a case divulge to the police what had come to his knowledge professionally he would not be sent for, and loss of life or health would often result. There are other reasons why Dr. Levinson acted rightly, but the one reason given amply justifies Dr. Levinson's position.—I am, etc.,

Blindley Heath, Nov. 13th.

HUGH WOODS.

### RESEARCH IN GENERAL PRACTICE.

SIR,—In an article upon this subject in your issue of November 6th (p. 844) you comment upon the advisability of a plan to secure continuity of treatment through co-operation between general practitioners and specialists, and you point out that neither the earliest beginnings of disease nor the real end-results of treatment are now adequately known or recorded.

A practical scheme, initiated by the late Sir James Mackenzie, which attains both of these objects has been in operation for seven years at the James Mackenzie Institute for Clinical Research, St. Andrews. The recording and study of the early stages of disease by general practitioners are the primary objects of the institute, and post-graduate teaching is attempted. The pathologist of the institution, whose laboratory is in the building, is medical officer of health for the burgh; he is thus in daily personal touch with all the general practitioners. The staff includes consulting specialists in various departments. A complete system of filing and indexing of all records is in use. It

OBITUARY.

Nov. 20, 1926]

was the hope of the distinguished founder that similar institutes affording facilities for research to general practitioners would in time be established throughout the country—a hope which Dr. Forrester-Brown's article and your comment bring nearer fulfilment.  
I will be glad to give detailed information to anyone contemplating the inauguration of a similar scheme elsewhere.—I am, etc.,

J. HUNTER P. PATON,  
Secretary, James Mackenzie Institute for  
Clinical Research, St. Andrews, Fife.

November 9th.

PERSISTENCE OF TUBERCLE BACILLI IN BUTTER  
FROM TUBERCULOUS MILK.

SIR,—In reply to Dr. Moore's letter of October 14th (BRITISH MEDICAL JOURNAL, November 6th, 1925), referring to an article of mine published in your issue of October 9th (p. 637), may I say:

(1) I was fully cognizant of the American work to which Dr. Moore calls attention, but cannot accept his view that in this country the persistence of tubercle bacilli in butter was generally recognized by those concerned with the epidemiology of tuberculosis. The variability in the results of investigations confirms my view.

(2) As regards pasteurization, "the modern significance" of this term varies with different operators as regards time, temperature, and technique. For example, under Danish law the temperature selected to which milk must be heated has been 80° C., and yet Dr. Moore regards 70° C. as too high. In view of this lack of uniformity of method I employed three different temperatures, and "ingenuously" described the method used; if it does not coincide with what pasteurization connotes to Dr. Moore's mind I cannot help it; it at least corresponds to pasteurization as employed in numerous instances, as well as probably covering the thermal death point of tubercle bacilli, the real point at issue.

(3) I would invite Dr. Moore to re-read the last paragraph of my communication, especially noting the reservation it contains.—I am, etc.,

H. A. COOKSON.

CLOTHING AND CATARRHS.  
SIR,—Most professions and callings tend to induce in their rotaries a particular type of mentality. The study and practice of medicine tends to produce the pundit. Of this unfortunate fact the letter of Mr. A. R. Jordan in your last issue affords a striking example. If I understand him correctly, he accuses me of gross dishonesty in dealing with a scientific subject in a lay paper, because I therein expressed opinions which do not happen to coincide with his own. In support of this charge he says that I "must be aware that the respiratory function of the skin in man is almost negligible." I protest that I am aware of nothing of the sort. I am, of course, aware that such is the ordinary teaching; but I claim as much right honestly to differ from the ordinary teaching as I can afford sincerely to admit Mr. Jordan's right to embrace it. There is no such thing as a monopoly of knowledge in such matters.

Thirty years ago the pundits were solemnly informing us that the influence of the thyroid gland upon the human economy was "almost negligible." A little later they assured us that the appendix was a vestigial organ whose influence for good or ill was "almost negligible." Later still they asserted that the effects of oral sepsis and intestinal stasis were both of them "almost negligible." But it is not necessary to multiply instances. Medicine being a progressive science, differences of opinion are not only inevitable, but desirable; but it is a sad discredit to the profession when they are not allowed to obtain without the imputation of unworthy motives. For no better reason than a perfectly legitimate difference of opinion as to the importance of the respiratory function of the skin, Mr. Jordan publicly impugns my scientific sincerity—an act of crude discourtesy for which it is difficult to find an excuse.—I am, etc.,

LEONARD WILLIAMS.  
London, N.W.1, Nov. 15th.

MALIGNANT DISEASE OF THE UPPER AIR AND  
FOOD PASSAGES.

SIR,—In the course of the discussion upon malignant disease of the upper air and food passages (BRITISH MEDICAL JOURNAL, November 6th, p. 828) I am reported as having said that I "rather doubted the benefit to be gained from preliminary gastrostomy." It so happens that I expressed precisely the opposite view, and am, and have always been, an advocate of an early gastrostomy in obstructive disease of the oesophagus, just as I have been an equally ardent advocate of early tracheotomy in obstructive disease of the larynx where the course of pathological events indicates in unmistakable terms the advent of air hunger in the immediate future.—I am, etc.,

W. MILLIGAN.

Manchester, Nov. 12th.

THE CANCER PROBLEM.

SIR,—Owing to an oversight two errors occurred in one of the charts published in my Lloyd Roberts memorial lecture in your last issue. The mistake was discovered too late for correction. In Chart 9 an experiment is represented in which two fowls were used, Nos. 520 and 521. In the right breast of 520 1 c.cm. of acriflavine-treated tumour extract was injected and not 0.5 c.cm. as represented; in the left leg of 521 a mixture of 0.5 c.cm. of the same acriflavine-treated extract and 0.5 c.cm. of a first subculture of a rat carcinoma in broth-embryo medium. The remainder of the chart is correct.—I am, etc.,

W. E. GRE.

London, N.W.7, Nov. 12th.

"RISING OF THE LIGHTS."

SIR,—When practising in North Worcestershire early this century I often heard "good women" speak of "rising of the lights," but was never able to discover the clinical entity so designated.  
A line of treatment of certain efficacy I did, however, manage to get confided to me: it is to get the patient to swallow liquid mercury. The mercury weighs the lights back into position, then all is well!—I am, etc.,

EDGAR L. COLLIS.

Obituary.

DR. ARTHUR WILLIAM SCATLIF, who died on October 14th, was the second son of the late Dr. J. P. Scatliff of Sloane Street, London, and received his medical education at St. George's Hospital. He obtained the diplomas of L.S.A. in 1876, of L.R.C.P. Edin. and L.M. in 1877, of L.R.C.S. in 1879, and the D.P.H. of the English Conjoint Board in 1889. After serving as assistant to the medical registrar of St. George's Hospital he practised in Margate for twenty-five years, holding the post of medical officer of health for fifteen years, and also that of police surgeon. In 1904 he joined the Church Missionary Society as a medical missionary in Fuhkien, where he founded the large men's hospital in Futsing, and lectured on hygiene and bacteriology at the Medical College.

We regret to announce the death of Major CHARLES LOUIS WILLIAMS, I.M.S. (ret.), who died on October 31st at Banstead, Surrey, in his sixty-second year. He was educated at Liverpool College and Edinburgh, where he graduated M.B., C.M. in 1886, later taking his M.D., M.R.C.S., and D.P.H. He served for seventeen years in India, during which time he held the post of surgeon at the Madras General Hospital, civil surgeon at various military stations, and other appointments. He retired in 1906, and on his return to England was appointed medical superintendent of the Booth Line in Liverpool. In 1913, after four years of laboratory work at Liverpool University on tropical and cancer research, he was appointed resident medical officer to Glenalmond, one of Scotland's public schools, but left that to join the army in 1914 and resume his surgical work. To Major Williams's great disappointment he was not allowed to go overseas because of his health.

record in India, but from 1914 to 1920 he served as senior or divisional surgeon in various hospitals at home. After demobilization he held the post of resident operating surgeon in the Ministry of Pensions hospital at Birmingham until October, 1921, from which time until the end of 1924 he served on the Pensions Appeal Tribunals. The remaining two years of his life were devoted to the pursuit of his favourite hobby, ornithology, of which throughout his life he was an enthusiastic and devoted student.

## Medico-Legal.

### "ADMINISTRATION" OF DANGEROUS DRUGS.

#### JUDICIAL INTERPRETATION OF "DIRECT PERSONAL SUPERVISION."

A Divisional Court of the King's Bench Division (the Lord Chief Justice, and Avory and Salter, JJ.), on November 12th, allowed the appeal of Dr. G. C. Kingsbury, who is both a practising barrister and a registered medical practitioner, against a conviction by the late Lord Mayor of London (Sir William Pryke) for failing to enter in a register or day-book the name and address of a patient whom he was endeavouring to cure of the morphine habit by gradual reduction of doses.

The hearing before the late Lord Mayor was reported briefly in the BRITISH MEDICAL JOURNAL of March 13th at page 509.

#### The Home Secretary's Regulations.

By Section 13 of the Dangerous Drugs Act, 1920, as amended by Section 2 of the Dangerous Drugs and Poisons (Amendment) Act, 1925: "Any person (1) who acts in contravention of or fails to comply with any regulation made against this Act . . . shall be guilty of an offence against this Act." Under powers conferred by Section 7 of the 1920 Act, the Home Secretary issued a series of regulations on May 20th, 1921. Regulation 4 authorized the dispensing of drugs in pursuance of a prescription given by a qualified medical practitioner, and the supply of drugs by a qualified medical practitioner or registered veterinary surgeon, who dispensed his own medicines in accordance with the provisions of Regulation 9, "provided that administration of the drugs by or under the direct personal supervision of a duly qualified medical practitioner . . . shall not be deemed to be supplying the drug within the meaning of this and the following regulations."

Regulation 9 provides that every person supplying drugs must keep a register in the form, and containing the particulars shown, in Schedule I to the regulations, which has columns for "name and address of person, body, or firm to whom sold and supplied," and further provides that a qualified medical practitioner who records in a day-book particulars of drugs supplied, together with the name and address of the patient and date of supply, may, in lieu of keeping the register, enter in a book to be kept for the purpose references under the appropriate dates to the records in the day-book.

#### Case Stated by the late Lord Mayor.

The facts of the case stated by the late Lord Mayor showed that Dr. Kingsbury had never accepted a fee from any patient since his call to the Bar in 1902, and when since the passing of the Dangerous Drugs Act he undertook to try to cure two former patients by gradual reduction of doses he bought drugs at a cost of £25, making no charge to the patients. One of the patients he cured before the end of 1924. During the period covered by the summons—August 20th, 1925, to February, 1926—he was treating a City worker, and had succeeded in reducing the drug taken to one-fiftieth of the daily dose taken at the beginning of the treatment. He had seen this patient every other day, even during his own holidays, and on the days of his visits had left with the patient the necessary supply of morphine for the proper doses for that day and the succeeding day, with instructions as to time and methods of taking it. He did not actually see the patient take the drug, but stated that he would have known if the patient had been getting morphine from other doctors. He did not disclose the name and address of the patient in any book. The appellant's main contention was that the proviso to Regulation 4 completely exempted him from the requirements of Regulation 9 as to the keeping of records, as the administration of drugs by or under the direct personal supervision of a duly qualified medical practitioner was not deemed to be supplying dangerous drugs within the meaning of the regulations. Further, he contended that Regulation 9 was *ultra vires* as not being authorized by Section 7 of the Act of 1920. The late Lord Mayor, being of opinion that Regulation 9 was valid, and that the proviso to Regulation 4 did not apply to Dr. Kingsbury, found him guilty of an offence against the Act, and fined him £25 and £10 10s. costs.

Mr. Norman Birkett, K.C., and Mr. Arthur Davis (instructed by Messrs. Ashurst, Morris and Co.) appeared for the appellant, and Mr. H. D. Roome (instructed by the Director of Public Prosecution) appeared for the respondent.

#### The Appellant's Argument.

Mr. Birkett, in his argument, said that Dr. Kingsbury had merely been found guilty of a technical offence in not keeping records. There was no reflection whatever on his character. The prosecution had said: "You have not kept the record required," and Dr. Kingsbury had replied: "I have done all that the law requires of me." The Act of 1920 was designed to deal with the improper trafficking in drugs and not to interfere with the normal use of them by doctors or with the confidential relations between doctors and their patients. "Direct personal supervision" in no way

implied the physical presence of the practitioner. The course which Dr. Kingsbury followed of making regular visits at short intervals and of giving to the patient only enough morphine to last him in accordance with the treatment till the next visit was the normal ordinary practice, which the highest people in the medical profession had recommended in their report on drug addiction for the guidance of the Ministry of Health. If a doctor required the patient to take minute doses at frequent intervals it would need a millionaire to undergo treatment if the doctor had always to be personally present. There was no evidence to justify the finding that the administration of the drug had not been under the direct personal supervision of Dr. Kingsbury.

#### The Respondent's Argument.

Mr. Roome submitted that "direct personal supervision" were the strongest words that could be used. Here the patient had been supplied with a quantity of the drug intended to last two days, which the patient might have taken within a few hours.

The Lord Chief Justice: Suppose a doctor personally administers a dose of medicine to a patient at 11 a.m., and says: "If his temperature rises a degree give another dose to-night; otherwise wait till I see him again at 11 a.m. to-morrow." Would that be "direct personal supervision"?

Mr. Roome: It would be too oppressive to hold otherwise.

Mr. Justice Avory: Test it another way: If another doctor were called in in consultation, would he not say: "What have you been administering?" and would not Dr. Kingsbury reply: "I have been administering such and such doses of morphine." Suppose then the other doctor asked: "Did you personally supervise the administration?" would he not receive the reply: "Yes; I saw the patient every other day, and specified precisely how much he was to take, and watched the effect." Could you say that that would be inaccurate?

Mr. Roome thought it would be too high a description of what was done. Anyhow, it was for the appellant to prove he fell within the proviso. The regulations protected addicts from themselves, and were designed to prevent a double supply by more than one doctor. Surely it was no great hardship that a name and address should be divulged?

#### Judgement allowing Appeal.

The Lord Chief Justice, in allowing the appeal, said that at the close of the argument the question which really emerged was a simple one, capable of brief statement. It was this: Upon the true construction of the proviso to Regulation 4 was that which was here complained of "administration" of morphine "by or under the direct personal supervision of a duly qualified medical practitioner"? When the special case stated by the late Lord Mayor of London was examined no doubt was left of the contention made by the prosecution in the court below. He would read its *ipissima verba*: "That in Regulation 4 the words 'administration of the drug by a duly qualified medical practitioner' meant that the doctor must administer every dose by his own hand, and that administration under the direct personal supervision of a duly qualified medical practitioner meant that the doctor must be present, and either see the patient administer each and every dose to himself or see the nurse or other person administer such dose to the patient." Whatever else might be said of that contention, it was wholly free from ambiguity, and that contention was held to be right by the late Lord Mayor. His lordship then read the facts set out in the case stated, and observed that the respondent's counsel (Mr. Roome) now no longer contended that, subject to proper provisions and precautions, the actual personal presence of the doctor was necessary. But it was further contended that when the terms of the proviso were contrasted with the body of Regulation 4, the word "administration" was confined to a particular emergency as contrasted with regular supply. It was said that if that were not so great mischief might arise to the patient himself, because he might consume a quantity of the drug without a record being made, and have the opportunity of obtaining further supplies. But the court had to construe what the regulations made by the Home Secretary under Section 7 of the Dangerous Drugs Act, 1920, actually said, and not what they might have said. In Regulation 5 there occurred the words "in case of emergency," and it would have been easy to have put those words in Regulation 4. But the question of amending the regulations was not one for that court, but for the Government department concerned. It seemed to his lordship as impossible to limit the words of the proviso to Regulation 4 to cases of emergency as it was to limit personal supervision to cases where the doctor was personally present. Looking at the words of Regulation 4 as part of a much larger whole, his lordship did not think that it was restricted to the limited meaning contended for, and once that had gone, on the facts of this case, he thought that there was direct personal supervision. His lordship expressed no opinion as to amendment of the regulations, but the decision of the court below could not be supported, and the appeal must be allowed with costs.

Avory and Salter, JJ., concurred.

#### A DANGEROUS DRUGS PROSECUTION.

At the Central Criminal Court, on November 15th, the jury, on the direction of the Common Serjeant (Sir Henry Dickens, K.C.), found John Kynaston, retired constable, R.A.M.C., guilty of aiding and abetting, g Rowland (medicinal opium), contrary to a regulation under the Dangerous Drugs Act, 1920, a nominal fine of £10 being imposed. The proceedings before the Marlborough Street magistrate are reported in the BRITISH MEDICAL JOURNAL of October 16th, at page 716.

Mr. H. D. Roome, for the Director of Public Prosecutions, said the defendant was summoned before the Marlborough Street

magistrate, and had chosen to exercise his right to trial by jury. Under the Dangerous Drugs Act no one was allowed to be in possession of any of the drugs prohibited in the regulations issued thereunder unless he was licensed or got them on the prescription of a "duly qualified medical practitioner"—that had a simple meaning—a person on the *Medical Register*. The defendant was not now a registered medical practitioner, but he still practised as a doctor. His name was removed from the *Register* in 1922, but he could still practise subject to the loss of certain privileges, one being that he might not deal in dangerous drugs. Mr. Pawsey, registrar of marriages, Marylebone, on August 25th was suffering from nasal catarrh, and the defendant gave him a prescription, the first thing mentioned being "powdered opium." The prescription was signed "Lieut.-Colonel John Kynaston, R.A.M.C., ret., M.R.C.S. and L.R.C.P. (London)." He had not the right, as a matter of fact, to the letters "M.R.C.S." and "L.R.C.P.," because he had been deprived of both diplomas.

Mr. Norman C. King, Registrar of the General Medical Council, said the defendant's name was removed from the *Medical Register* in May, 1922, for advertising.

The defendant stated that the removal of his name from the *Medical Register* was illegal, because the Council had allowed Sir George Newman, whom the defendant described as "a tainted judge," to be present at the inquiry after he (the defendant) had challenged him.

The Common Serjeant pointed out that the question whether the defendant's removal was legal or not was irrelevant.

In evidence, the defendant said he had a perfect right to the titles of M.R.C.S. and L.R.C.P. until the colleges concerned gave him a definite assurance on what statutory authority they based their right to remove his name from their rolls. He had notified the colleges that he intended going on using the letters until they did. He claimed that under the Dangerous Drugs Act he was entitled, as a qualified man, to prescribe the drugs, and he submitted that "duly qualified medical practitioner" in the regulations did not necessarily mean registered.

The jury having returned a verdict as directed, Mr. Roome said there was nothing whatever against the defendant, but the authorities brought proceedings because they were anxious to make it clear that only registered medical men could prescribe dangerous drugs.

The Common Serjeant said he imposed a nominal fine in view of the fact that proceedings were taken with the object of making clear the meaning of the Dangerous Drugs Act, and in view of the fact that the defendant was perfectly *bona fide* in his views. If he (the Common Serjeant) was wrong in his interpretation of the law, then the Court of Criminal Appeal would set him right. The defendant intimated that he would probably appeal.

#### TESTS FOR DRUNKENNESS.

A CASE, turning largely upon the question of tests for drunkenness, was tried at the Central Criminal Court before Mr. Justice Greer on November 15th and 16th. The accused was Henry William Franklin, aged 31, a chartered accountant, of London, who was committed from Epsom for having been drunk in charge of a motor car, and by negligence causing the death of one person and grievous bodily harm to three others, all of whom were in a motor-cycle combination with which he collided on the road between Leatherhead and Kingston on October 9th.

One of the witnesses called for the prosecution stated that, on seeing the accused immediately after the accident, he came to the conclusion that he was drunk—his breath smelt of alcohol, and his manner was peculiar. The police sergeant who was called to the scene also testified that the accused was drunk, and when this witness was asked why he was of that opinion, he said it was because the man swayed backwards and forwards, was unsteady on his feet, and thick and slow of speech. The police inspector at Leatherhead also said that when brought to the station the accused was unsteady and smelt strongly of drink. The police surgeon examined him three-quarters of an hour after the accident and certified that he was drunk. The accused asked that his own doctor in London might be sent for; there was some delay in telephoning for this doctor; and when a call got through it was intimated that he could not attend owing to the distance and pressure of work. The accused then mentioned another doctor, Dr. A. V. Moberly of Surbiton, and Dr. Moberly, examining him two hours and five minutes after the police surgeon's examination, stated that he was not then drunk, and in the doctor's opinion could not have been drunk at the time of the accident. His Lordship called the police inspector back to the witness-box and questioned him as to the reason for the delay in summoning the doctor asked for by the accused. "It is your duty," said Mr. Justice Greer, "to help accused people to get their own doctor."

Dr. E. H. H. Granger, police surgeon for Leatherhead and district, testified that on examining Mr. Franklin he found him drunk and unfit to drive a motor car. He put Mr. Franklin through certain tests and also made a complete clinical examination. He got him to describe the journey he had just taken, in order to test his memory, and he got through this test fairly well. He showed, however, a certain lack of physical co-ordination. He was asked to walk along a board and along a line between two boards; he responded to the first of these tests tolerably, to the second badly. The whites of his eyes were bloodshot, and the pupils very much dilated. To test his powers of articulation he asked him to say "British constitution," and the response to this test was not well carried out. His pulse was very full in volume, and rapid, 120 to the minute. The whole examination took twenty-seven minutes.

Cross-examined by Sir Henry Curtis-Bennett, for the defence, Dr. Granger said that he took no account of the smell of the

breath. He was not aware that there was something wrong with the cartilage of the man's leg, which would prevent him responding successfully to the walking tests.

The test of walking along a line is one which a good many sober people could not manage?—It is a fair test for young and middle-aged men?

Did you put him through the Romberg test, in which a man stands with his heels together and closes his eyes, and it is observed whether or not he sways?—Yes.

That is a test in which a great many perfectly sober people fail?—No, I think not; but no test was considered by itself.

Do you think the Romberg test is of the slightest use?—It is a routine test employed.

Routine, whether a man has had an accident or not?—Certainly.

Do you take shock into consideration at all?—Yes, we take it into consideration.

Am I right in saying that a man who has suffered a shock will not be able to do the Romberg test?—I am not prepared to say whether you are correct or not.

How did he respond to the Romberg test?—He swayed.

The quick pulse is consistent with shock, excitement, anger, or even the strain of undergoing a medical examination?—Quite correct.

The pupils were dilated?—They were.

Dilatation of pupils is a very common symptom among people suffering from shock?—The dilatation of pupils occurring in severe shock tends quickly to wear off.

The eyes in shock react quickly to light?—They do.

But if the pupils are dilated as a result of drunkenness the reaction to light is very slow?—That is a question I am not prepared to answer. When light is allowed to fall on the pupil the pupil grows smaller. As to whether in drunkenness it grows smaller more quickly or more slowly I am not prepared to offer an opinion.

You examined his tongue?—Yes.

And even then you say nothing about the smell of drink?—I have said nothing about the smell of drink.

As to pronouncing "British constitution," is it within your recollection that the clerk at the police court, against whom there is not the slightest intimation, when he was reading over the depositions, stumbled badly over the words "British constitution," to the great amusement of the court?—You are quite wrong in making that statement.

Re-examined by Dr. A. D. Lucy for the prosecution, Dr. Granger said that he considered the smell of the breath a very misleading test in drunkenness. Apart from the tests he had described, he could not think of any other recognized or regular tests for drunkenness which were of the slightest use.

Evidence was then called for the defence. The accused's own statement, which was borne out by the evidence of certain companions, was that all the alcohol he had had on the day in question was half a pint of beer at lunch, a few sips of whisky later in the afternoon just before leaving London, and a small glass of whisky at Kingston a couple of hours later, about three-quarters of an hour before the accident.

After corroborative evidence (non-medical) had been given on this point, and of his control of his car earlier on the journey, His Lordship suggested that it was obvious that, unless all these witnesses were lying, the man was not drunk. The burden of proof that he was drunk was on the prosecution. No man could meet such a charge except in the way that defendant had met it, by calling people who testified that he was sober. Sir Henry Curtis-Bennett said that he had medical evidence to call in defence—the evidence of Dr. Moberly and of a specialist.

The jury, after consultation, without calling for the medical evidence, found that the defendant was not drunk, and this was dropped from the charge. The other parts of the charge were proceeded with, and in the result the accused was found not guilty of criminal negligence, and was discharged.

At the opening of the Manchester Assizes, on November 16th, the Grand Jury, on the advice of Mr. Justice Branson, threw out the bill for murder against Drs. A. S. Holden and F. L. Webster, but returned true bills for manslaughter and felony. The preliminary magisterial hearing of the case was reported in our last issue, at page 809, and the proceedings at the inquest in our issue of November 6th, at page 860.

#### Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

THE House of Commons this week considered and approved a supplementary vote of £3,250,000 for extra expenditure by the Ministry of Labour in helping local authorities to relieve destitution. A vote was also passed for expenses of the new broadcasting corporation and a money resolution discussed authorizing expenditure under the Housing (Rural Workers) Bill now before the House. Consideration of the Smoke Abatement Bill was due to commence in a Grand Committee of the House on November 18th.

The Committee stage of the Lead Paint (Protection against Poisoning) Bill was set down for Thursday in the House of Lords.

#### Infantile Paralysis.

SIR KINGSLEY WOOD, in an answer to Captain Fairfax, on November 11th, said the number of cases of infantile paralysis notified at Leicester in the two weeks ended November 6th was 15, compared with 54 in the previous fortnight. There were no fresh cases in

Broadstairs in the week ended November 6th. Infantile paralysis had been prevalent in this country for many years. It was one of a group of epidemic nervous diseases of which our knowledge was still very imperfect, but research was being prosecuted, and it was hoped that means would be discovered which would lead to the exercise of more effective control over its spread. The Ministry of Health had closely watched the outbreaks, and a specially skilled member of its staff had visited the areas most affected to assist the local authority in providing for the supervision and control of the outbreaks. Sir Kingsley Wood did not think that the number of deaths resulting from the present outbreak was large. Replying to Mr. Everard, he supplied the following table of cases of infantile paralysis (acute poliomyelitis and acute polio-encephalitis) notified in England and Wales each month since May:

*Notifications of Infantile Paralysis (Acute Poliomyelitis and Acute Polio-encephalitis) in England and Wales (1925).*

| Month.           | Acute Poliomyelitis. | Acute Polio-encephalitis. | Total Cases of the Disease. |
|------------------|----------------------|---------------------------|-----------------------------|
| May ... ..       | 18                   | 3                         | 21                          |
| June ... ..      | 29                   | 3                         | 32                          |
| July ... ..      | 56                   | 7                         | 63                          |
| August ... ..    | 148                  | 16                        | 164                         |
| September ... .. | 215                  | 7                         | 222                         |
| October ... ..   | 319                  | 54                        | 373                         |
| Totals ... ..    | 785                  | 90                        | 875                         |

On November 16th Sir K. Wood, replying to Captain Fairfax, said that there had been no further deaths from infantile paralysis in Leicester since October 25th last. Three more deaths had occurred as a result of the Broadstairs outbreak.

#### Encephalitis Lethargica.

On November 16th Sir K. Wood told Captain Fairfax that the total number of cases of encephalitis lethargica notified in England and Wales during the present year up to November 6th was 1,946, and the approximate number of deaths up to the end of August was 935. The Minister of Health understood that the Medical Research Council would shortly publish a report on this disease, containing a statement of the progress which had been made in the search for its cause. Until this had been discovered, and means had been devised for controlling the development and spread of the disease, it was necessary to rely on those methods which had proved efficacious in dealing with other infectious diseases.

#### Destitution and Malnutrition.

Mr. Chamberlain, in replying to a short debate on the way in which boards of guardians had met hardships due to the strike, said that on the whole they deserved the highest possible credit. There had been no evidence of malnutrition, and repeated reports had been received to the effect that the children were actually better fed than they were when their fathers were at work. By a system of block grants, when it was possible to allocate them on a fair and proper basis, taking into account not merely population but also capacity to pay, as measured by rateable value, it might be possible to devise a scheme which would bring relief to necessitous areas without doing injustice to any other part of the country. That was the policy to which he looked for a permanent solution of the problem.

**Lead Poisoning.**—Mr. Rhys Davies asked the Home Secretary whether his attention had been called to three serious cases of lead poisoning during 1926 at one factory in the Potteries, affecting young women aged 19, 23, and 26, one of whom had died. Sir William Joynson-Hicks replied that no case of lead poisoning had been reported in this factory from 1913 till this year. The factory had been reconstructed in 1913, but it appeared that recently the exhaust ventilation had not been efficiently maintained. The case was a bad one and had been actively taken up by the Home Office.

**Disability Pensions for Lethargic Encephalitis.**—On November 15th Lieut.-Colonel G. F. Stanley (Parliamentary Secretary to the Ministry of Pensions) informed Mr. R. Morrison that disability pensions were being paid in respect of encephalitis lethargica due to war service. The statistical records of the Ministry did not enable him to state the precise number of cases.

**Report of the Lunacy Commission.**—On November 15th Mr. Chamberlain informed Sir W. Davison that the report of the Royal Commission on Lunacy was receiving careful consideration. Until the recommendations had been examined in all their bearings legislation which the Government might be able to introduce. **Committee on Nursing Homes.**—On November 15th Mr. Chamberlain informed Mr. Hurst that the report of the Select Committee on Nursing Homes was under consideration. He was not able to make any statement in regard to legislation to give effect to the committee's recommendations.

**Veneral Disease in India.**—On November 16th Earl Winterton (Under Secretary for India) stated that a committee was assembled in Simla, in October last, to consider whether any modification in policy in combating venereal disease among British troops was

desirable in the light of experience during recent years. The committee was composed of officers commanding the 2nd Battalion Lancashire Fusiliers and the 2nd Battalion Lincolnshire Regiment, the chaplain to the Metropolitan, the Consulting Dermatologist, Army Headquarters; the Deputy Director, Personal Services, Army Headquarters; and Deputy Assistant Adjutant-General, Army Headquarters. The report of the committee was under the consideration of the Commander-in-Chief.

**University of London.**—On November 16th the Chancellor of the Exchequer informed Mr. Campbell that the official reports of the deputations which he received from the University of London in June last had been communicated to the university authorities. He did not, however, think it desirable to publish them. Replying to Dr. Little, the Chancellor said that it would be unusual to lay on the table of the House of Commons reports of deputations to Ministers.

#### Notes in Brief.

In England and Wales during 1925, 4,054 persons were found by coroners' verdicts to have committed suicide. In England, 2,636 persons were males and 1,164 females; in Wales, 149 males and 55 females.

In England, Scotland, and Wales, 511,890 houses have been completed since the war with State assistance and approximately 296,900 without State assistance. The number of houses now completed, under construction, or authorized under the Housing Acts is 706,699.

In the six months ended September, 1926, £13,000,000 was distributed as out-relief in England and Wales, compared with £7,000,000 in the same period of 1925.

Inspection by the Ministry of Health has not shown that the refuse dumps near Purfleet and Tilbury are a menace to health, but possible improvements in the collection and disposal of London refuse are being investigated.

The number of steel or cast-iron houses authorized in England and Wales is 993, excluding those erected for demonstration purposes.

Mr. Chamberlain states that 491 new officials have been appointed in his department since January 1st, 1926, of whom 423 are established.

The Minister of Health is advised that there are no medical grounds to support a proposal to make it compulsory for the bodies of persons who died from cancer to be cremated.

## The Services.

### HONORARY SURGEON TO THE KING.

MAJOR-GENERAL J. S. GALLIE, C.M.G., D.S.O., late R.A.M.C., has been appointed Honorary Surgeon to the King, with effect from September 16th, 1926, in succession to Major-General D. J. Collins, C.B., C.M.G., late R.A.M.C., retired.

### DEATHS IN THE SERVICES.

SURGEON LIEUT.-COLONEL ARTHUR TOMES, Bengal Medical Service (ret.), died at Exmouth on November 1st. He was born on February 18th, 1851, the son of Robert Tomes of Alcester, Warwickshire. Educated at the Middlesex Hospital, where he gained the Broderip scholarship, he took the M.R.C.S. and L.S.A. in 1873, the S.S.C. of Cambridge in 1876, and the M.D. with honours at Brussels in 1885. He entered the I.M.S. as surgeon on March 31st, 1876, passing first into and out of Netley, and gaining the Herbert prize there. He became surgeon lieutenant-colonel after twenty years' service, and retired on October 13th, 1897. Nearly all of his service was spent in civil employ in Bengal, where he was recognized as being likely to rise to the highest appointments, when his career came to a most unfortunate end. He had the misfortune to inoculate himself while performing an operation, and suffered from blood poisoning so severely that, after a year's sick leave, he was unable to rejoin, and had to retire with only twenty years' service.

## Universities and Colleges.

### UNIVERSITY OF CAMBRIDGE.

with Prize, for the best M.B. thesis during an awarded to A. J. Copeland (Pembroke).

Hart Memorial Scholar of the British

Medical Association in 1923-24.

At a congregation held on November 13th the degree of M.B. was conferred on F. R. Sandford.

### UNIVERSITY OF LONDON.

#### Lectures.

PROFESSOR H. E. ROAF will give two lectures on colour vision at University College, London, at 5 p.m., on December 1st and 8th. A course of five lectures on the influence of environment on bacteria will be given by Dr. F. W. Twort, superintendent of the Brown Institution, at 4 p.m., in the theatre of the Royal College of Surgeons, on December 6th, 7th, 9th, 13th, and 14th. As previously announced, the Semon Lecture on nervous affections of the oesophagus will be delivered by Dr. A. Brown Kelly, at the Royal Society of Medicine, on December 2nd, at 5 p.m. Admission is free to all these lectures, and tickets are not required.

### UNIVERSITY OF GLASGOW.

At the graduation ceremony held on November 13th the following were among the degrees conferred:

M.D.—Dorothy B. Thomson (with high commendation).

M.B., Ch.B.—Henry D. Matheson.

# NATIONAL UNIVERSITY OF IRELAND.

At a meeting of the University held on Saturday, November 6th, for the purpose of conferring degrees and other academic distinctions at University College, Dublin, Dr. Denis J. Coffey, M.A., M.B., LL.D., President of University College, Dublin, and Vice-Chancellor of the University, presided, and conferred the following degrees in the Faculty of Medicine:

M.D.—W. J. Coyne.  
M.Ch.—F. J. Morris, M. J. Smyth.  
M.A.O.—C. Martin.

M.B., B.Ch., B.A.O.—M. L. Kennedy, E. Keenan, A. T. McKay, W. H. Ashmore, F. J. Byrne, Louisa M. Cullen, J. V. H. Cusson, G. Davis, J. T. Eastace, M. A. Forrester, F. G. Friel, J. Glynn, P. Hennessy, E. Kilmartin, J. G. McGilligan, J. J. Maher, J. O. Manning, D. Moriarty, J. Mowbray, Jane A. M. Nagle, L. O'Connor, L. M. O'Hara, Margaret M. Partridge, Sarah Walsh.

D.P.H.—C. M. Stuart, I. D. Brady, C. F. Keane, M. F. Dodd, M. O'Sullivan.

DIPLOMA IN MENTAL DISEASES.—J. Dunno.

# ROYAL COLLEGE OF SURGEONS OF ENGLAND.

An ordinary Council meeting was held on November 11th, when the President, Sir Berkeley Moynihan, Bt., was in the chair.

## Deaths.

The death, on November 4th, of Mr. James Ernest Lane, past-member of the Council and of the Court of Examiners, was reported, and a vote of condolence was passed.

The death was also reported of Mr. Douglas Gabell, member of the Board of Examiners in Dental Surgery. The vacancy thus occasioned will be filled up at the next meeting of the Council on December 9th.

## Diplomas of Membership.

Diplomas of Membership were granted to 179 candidates. (The names were published in the report of the comitia of the Royal College of Physicians of London (BRITISH MEDICAL JOURNAL, November 6th, p. 851).

## Revision of By-laws.

Alterations in Sections 4, 8, 20, 25, and 26 of the By-laws were approved, and the solicitor of the College was instructed to submit the new By-laws to the proper authorities for sanction and ratification.

## Court of Examiners.

It was decided to appoint two additional members of the Court of Examiners at the next meeting of the Council on December 9th, and the vacancy occasioned by the resignation of Mr. Pendlebury will be filled up at the same time.

## Portrait of Sir Henry Morris.

A portrait, by W. W. Ouless, R.A., of the late Sir Henry Morris, Bt., past-President of the College, offered to the College, in accordance with his testamentary instructions, was accepted with appreciation.

# Medical News.

PRINCESS MARIE LOUISE opened a new artificial sunlight clinic at the Mildmay Memorial Hospital, Newington Green, on November 13th. The clinic is equipped with carbon arc and mercury vapour lamps for general and local irradiation, and is associated with the maternity and child welfare organizations in the district; patients are received on the recommendation of medical practitioners.

THE long association of the late Dr. Frederick B. Hulke with the Victoria Hospital, Deal, which he served as senior surgeon from 1897 to 1925, was commemorated on November 6th by the unveiling of his portrait, presented to the hospital by the House Committee, and the naming of a ward of the institution after him. On the same day a flagstaff erected in the grounds of the hospital by the Deal and Walmer Volunteers Old Comrades' Association was dedicated to his memory.

DR. LÉOPOLD MAYER of Brussels has been elected general secretary of the International Society of Surgery.

THE Prince of Wales's Hospital Reunion Association will hold its annual dinner at the Trocadero Restaurant on Friday, November 26th, at 8 for 8.15 p.m., with Mr. J. B. Banister in the chair. The price of the dinner will be 12s. 6d. (exclusive of wine) for members and their guests. The secretaries are Dr. Browning Alexander, 143, Harley Street, W.1, and Dr. S. O. Rashbrook, 7, Wellesley Road, Chiswick, W.4.

THE annual dinner of the London School of Medicine for Women will be held at the Savoy Hotel on Thursday, December 2nd.

THE annual dinner of the Royal Society of Tropical Medicine will be held at the Hotel Victoria, Northumberland Avenue, W.C.2, on Monday, November 22nd. The Earl of Balfour will be the principal guest, and the president of the society, Dr. Andrew Balfour, will take the chair at 8 p.m.

THE annual reunion dinner of the British Serbian Branch of the British Legion will be held on Saturday, December 4th, at 7.30 p.m., at the Victoria Mansions Restaurant, 24, Victoria Street, Westminster, with the president, Sir James Berry, F.R.C.S., in the chair. All who served in Serbia are invited, together with their friends. Tickets (price 7s. 6d.) may be obtained from the honorary secretary, Miss Marx, 24, Melcombe Court, Dorset Square, N.W.1.

THE annual congress of the Ophthalmological Society of the United Kingdom will be held at Liverpool on April 28th, 29th, and 30th next. Further particulars can be obtained from Mr. Charles Goulden, F.R.C.S., 79, Portland Place, W.1.

FROM May 16th to June 12th 894 fatal cases of plague occurred in Java.

THE Government of India has decided to make a donation of £250 to the funds of the Ross Institute and Hospital for Tropical Diseases, Putney Heath, S.W.

THE Fellowship of Medicine announces that on November 25th, at 5 p.m., Mr. Harold Chapple will lecture on the emergencies of pregnancy and parturition, at the house of the Medical Society of London, 11, Chandos Street, Cavendish Square. On November 23rd, at 11 a.m., Mr. B. Leggett will give a lecture demonstration at St. Mark's Hospital on radiological investigation of the colon and rectum. These lectures are free to members of the medical profession. A week's course will also be given at St. Mark's Hospital from November 22nd, including operations, demonstrations, and lectures. A late afternoon course (5 p.m.) from November 22nd to December 18th will be held at the West End Hospital for Nervous Diseases, 73, Welbeck Street, consisting of lectures and clinical demonstrations upon selected cases, and the London Temperance Hospital will hold a 4.30 to 6 p.m. course in medicine, surgery, and the specialties from November 29th to December 11th. Courses in obstetrics are available at Queen Charlotte's Hospital and the City of London Maternity Hospital. The Fellowship of Medicine has arranged with the Samaritan Hospital for Women for the provision of clinical assistantships, personal application for which should be made to the Fellowship. Practical courses in anaesthetics can also be provided. Copies of all syllabuses and of the general course programme may be obtained from the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1.

At the meeting of the Post-Graduate Hostel, Imperial Hotel, Russell Square, W.C.1, on Monday, November 22nd, at 9 p.m., Mr. H. J. Patterson, F.R.C.S., will speak on gastro-enterostomy: its role and ultimate results. On Thursday, November 25th, at the same hour and place, there will be a symposium on cerebral localization in the clinical subject, when Dr. Gordon Holmes, C.M.G., will take the chair, and the following will participate: Dr. W. J. Adie, Mr. Donald Armour, Mr. A. P. Bertwistle, Dr. Carmichael, Dr. Macdonald Critchley, Mr. L. Bathe Rawling, and Dr. F. M. R. Walshe. Dinner will be served at 8 p.m. (price 5s.), and coffee and biscuits at 10 p.m. (price 6d.). All medical practitioners are welcome.

A FILM for instructional purposes, showing the drill employed in applying the Thomas splint, has recently been prepared by the British Red Cross Society. A demonstration of the film will be given at the house of the Royal Society of Medicine, 1, Wimpole Street, W.1, at 5 p.m., on Monday, December 13th. Medical practitioners are invited to attend.

THE Australian Journal of Experimental Biology and Medical Science has been endowed with £5,000 by Sir Joseph Verco in order that it may become the property of the University of Adelaide, with whose medical school the donor has been prominently associated since its inception. Sir Joseph Verco, who received his medical education at St. Bartholomew's Hospital and graduated M.B.Lond. in 1875, proceeding M.D. in the following year, has held the posts of lecturer in medicine at Adelaide University for twenty-seven years, and has been president of the Royal Society of South Australia for nineteen years; he is also dean of the medical school, and an honorary curator of the section of mollusca of the South Australian Museum. He was president of the South Australian Branch of the British Medical Association in 1886-87.

As town planning is a matter of importance, not only to local authorities and their officials, but also to private interests, the part of the Annual Report of the Ministry of Health for 1925-26 which deals with this subject has been published separately. In addition to other matters it gives information as to the attitude of the Ministry on a number of points in connexion with town planning and with appeals relating to proposed developments. Copies, price 6d., may be purchased from the Stationery Office at the following addresses: Adastral House, Kingsway, London, W.C.2; York Street, Manchester; 1, St. Andrew's Crescent, Cardiff; or 120, George Street, Edinburgh; or through any bookseller.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9861, 9862, 9863, and 9864** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

**EDITOR** of the **BRITISH MEDICAL JOURNAL**, *Aitology Westcent, London.*

**FINANCIAL SECRETARY AND BUSINESS MANAGER** (Advertisements, etc.), *Articulate Westcent, London.*

**MEDICAL SECRETARY**, *Mediscra Westcent, London.*

The address of the Irish office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumshugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

### QUERIES AND ANSWERS.

#### FLIES IN BUTCHERS' SHOPS.

WE have received an inquiry from the London Retail Meat Traders' Association as to the best method of getting rid of flies from butchers' shops.

If the flies have been allowed to breed, screening is the best palliative, but the real remedy is prevention, by getting rid of their breeding places—offal and manure. An expert, to whom we have referred the matter, informs us that during the war in South Africa, where flies were a veritable plague (sharing, according to Kitchener, the first place with women), he found that sprinkling chloride of lime got rid of them from camps and messes. A good method for butchers' shops is as follows: After cleaning down the walls, etc., in the ordinary way, they should be treated with a solution of chloride of lime, and then sprayed lightly with paraffin. Of the last very little is needed, and if too much is used there is a risk of imparting smell and taste to the meat. Its action appears to be due to its preventing any flies that may enter from getting a foothold, but the chloride of lime will keep most away.

#### MAJORCA.

"D. F. H." asks for information about Majorca as a health resort, as to hotels, medical aid available, and the best route from England.

According to a statement in *Climatotherapy and Balneotherapy* by Sir Hermann and F. Parkes Weber (1907) Palma, the capital of Majorca, is built on a bay facing south, and is protected by the north-western mountain chain from the cold winds to which the Balearic Islands are exposed. It has a warm, moist, equable winter climate, with a mean winter temperature of about 52.5°. The accommodation at that date was limited, but the authors thought that at some future time the place might be visited by English invalids. It seems now to be believed that this time has come. The Spanish Travel Bureau, Ltd. (87, Regent Street, London, W.), inform us that a pamphlet on Majorca is in preparation and will shortly be ready. The best route is by Barcelona, which can be reached from London by way of Paris.

#### INCOME TAX.

##### Partnership—Succession.

"W. L. G." bought a one-third share in a practice as from October 1st, 1925, and has been assessed on the basis of his predecessor's earnings.

This is in accordance with the statute, Rule 11 applicable to Cases I and II, Schedule D, but if the new firm can show at the end of their first year (or part of a year) that the profits of the practice have fallen short from some specific cause—for example, because the practice is now worked from two houses instead of one—since or by reason of the change, then they can claim an adjustment of the assessment. It is, however, important to remember that the "profits" include the value of outstanding book debts earned by the new firm and not paid over; cash receipts are not a reliable basis of calculation where, as in this case, the old book debts are not being brought into the accounts.

#### Production of Bank-books.

"B. W." has been requested by the inspector of taxes to produce his bank pass-books for the six years ending June 30th, 1920; some of the books have been destroyed.

The inspector of taxes has no legal right to demand production of the bank-books, but the request is unusual, and the inspector may have, or may think he has, some special grounds for making it. In the circumstances "B. W." might usefully call on him and discuss the matter personally, inquiring what is the special reason for making so unusual a request, and write up more fully if he is unable to arrange a satisfactory settlement.

#### CHILBLAINS.

Dr. H. E. GIBSON (London) writes: As one who started this trouble when in the R.A.M.C. during the war, and has had it every winter since, I should like to suggest local treatment by ultra-violet rays. In my case it acts like magic, and is the only treatment I have found to do any good. Possibly general light baths, with or without diathermy to the hands and feet, might prevent a recurrence.

SIR ROBERT ARMSTRONG-JONES also writes to recommend ultra-violet rays. "Cases of marked bullous erythema due to chilblains have been relieved by one application of the ultra-violet light, and this treatment deserves to be recognized and acknowledged."

Dr. A. E. R. RUTHERFORD (Westbury-on-Trym) writes: "C. P. J." can hardly hope, I think, for much success in his treatment of chilblains, with calcium salts especially, unless he warns his patient to avoid fruits and drinks containing citric acid—oranges, lemons, lemonade, etc. Citric acid would, I believe, prevent the beneficial result which might otherwise be expected from the use of calcium salts, and perhaps from other forms of treatment as well.

### LETTERS, NOTES, ETC.

Dr. CHARLES PORTER (University of Witwatersrand, Johannesburg) asks us to say that he has recently been erroneously described in *The World's Health Book* (a Red Cross journal) as Lieutenant-Colonel, R.A.M.C. The initial letters should have been S.A.M.C.

#### MATÉ OR PARAGUAY TEA.

Dr. L. GWILLIM DAVIES (Histon) has sent us some dried leaves which he learnt were being sold under the trade name "Herven" and described as "the wonderful South American plant with marvellous tonic-restorative powers." The patient who first drew his attention to this preparation, and had been taking it (though not with his permission), told Dr. Gwillim Davies that the effect of the infusion was to "make her work and work, until she dropped with exhaustion." It occurred to him that the leaves might be those of the coca plant, or possibly maté. From personal experience he found that the leaves certainly had some stimulating property when drunk in infusion. The specimen forwarded to us has been examined on our behalf, and the analytical chemist's report is that it consists of the leaves of *Ilex paraguayensis*, the Brazilian or Paraguay holly, and contains no cocaine. The plant is used as tea in South America under the name of maté or Paraguay tea. Like tea it contains caffeine, tannic acid, and a volatile oil. Bentley states in his *Manual of Botany* that "its properties are similar to those of tea, but it is more exciting, and when taken to excess produces a kind of intoxication." It contains, according to Martindale's *Extra Pharmacopoeia*, 2.02 per cent. of caffeine, which is rather more than in coffee and rather less than in tea.

#### ENTERIC FEVER AND SEWAGE.

"M.O.H." writes: If enteric fever is caused by a specific bacillus, how does sewage matter, finding its way into drinking water or milk, cause the fever? I know of an outbreak in this locality some months ago; it was supposed to be due to drinking water which was polluted by sewage matter. The four families using the water from this well (being a country place) contracted the fever. None of the parties had been away; no case of enteric fever had been in the locality for years; no carrier could be traced. No doubt in a heap of decaying animal or vegetable matter we have numerous organisms (putrefactive), but can they be the cause of typhoid fever? Offensive smells may cause sick stomach headaches, etc., but they cannot cause a specific disease. In these cases I think we can account for the disease by what biologists call "variation" in organisms; for instance, the *Bacillus coli*, growing in a heap of decaying matter, may, in circumstances very favourable to its growth, undergo variation and become pathogenic, and even produce enteric. No biologist can, by observing the behaviour of germs in a test tube, give any guarantee as to variations which may take place in nature. As Professor Judd says: "The observer can never see all the variations in the test tube. This is a somewhat puzzling problem, and I would like to have the opinion of some of your readers on it."

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 43, 44, 45, 46, 47, 50, and 51 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 48 and 49.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 223.

# British Medical Association.

## PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, NOTTINGHAM, 1926.

### SECTION OF MEDICINE.

F. H. JACOB, M.D., F.R.C.P., President.

#### DISCUSSION ON BLOOD TRANSFUSION IN THE TREATMENT OF DISEASE.

##### OPENING PAPERS.

I.—**SIR HUMPHRY ROLLESTON, BART., K.C.B., M.D., F.R.C.P.,**

Regius Professor of Physic, Cambridge.

**FROM:** considering the position of blood transfusion as employed at the present day it may be well, by way of introduction, to give a brief account of the history of the subject; for though it is only in recent years that transfusion has been employed to any extent, the idea is centuries old, an attempt having been made as far back as the middle of the seventeenth century. From that date down to the early years of the present century experiments were made at fairly wide intervals of time, as recorded in the following note.

##### Historical Note.

In his admirable monograph Geoffrey Keynes<sup>1</sup> has gone fully into all the aspects of transfusion, including the history, as would naturally be expected from such an eminent bibliophile. In his charming account of early science in Oxford R. T. Gunther quotes a letter of John Aubrey, the antiquary, to the effect that the idea of curing "diseases" by transfusion of blood out of one man into another "arose in the mind of Francis Potter, B.D., Fellow of Trinity College, Oxford, about 1639, from reflection on Ovid's story of Medea and Jason, and that about 1650 these two friends tried the operation unsuccessfully on a hen. Aubrey read a letter from Potter on the subject to the Royal Society, and had it entered in their books, "for Dr. Lower would have arrogated the invention to himself." The share of Sir Christopher Wren in bringing up the subject and Richard Lower's experiments at Oxford in 1665 (published in 1666) are historical. As to the priority of the first transfusion on the human subject, Keynes unhesitatingly gives the credit to Jean Denis of Montpellier, physician to Louis XIV, but Lower and Edmund King were close upon him in November, 1667, in transfusing Arthur Coga, an indigent Bachelor of Divinity of Cambridge, with the blood of a sheep. After enthusiastic imitations, catastrophes led to the abeyance of transfusion. "As in private duty bound" I should refer to the much later experiments of Sir Busick Harwood, which are briefly mentioned in a footnote (2 by himself) in Hulton, Shaw, and Pearson's abridgement of the Philosophical Transactions of the Royal Society in connexion with Oldenburg's paper on blood transfusion in the *Philosophical Transactions* for 1667 (p. 517). This footnote gives an account of Harwood's experiments in 1785: a dog was transfused from the carotid of a sheep, and fever resulted after twenty-four hours, though the dog survived. Harwood ascribed this fever to "the preternatural degree of stimulus occasioned by the highly oxygenated arterial blood into the right side of the heart"; he accordingly repeated the transfusion from the jugular vein of the sheep, with the expected result that the animal did not suffer the least inconvenience. Harwood satisfied himself that the blood of a herbivorous animal can be substituted for that of a carnivorous animal, and urged it for man, though apparently he did not practise his advice; but it may be noted that Cruchet and Ragot have recently transfused eighteen patients with sheep's or horse's blood, with improvement in fifteen cases. Apart from small resuscitations of the method, chiefly by Blundell and obstetricians from 1818 to 1824, and between 1860 and 1880 in Germany, and by von Bergmann's monograph in 1883, blood transfusion was practically abandoned; thus in 1889, in his conclusion to three lectures on the physiology, pathology, and practice of blood transfusion, William Hunter wrote: "For practical purposes all the advantages to be gained from transfusion may be equally well and more readily obtained by infusion of a neutral saline solution of common salt." Blood transfusion did not become popular until after the description of the four blood groups (Jansky 1907; Moss 1910), which rendered grave accidents preventable. During the war a great impetus was given to its employment, and it is now a very common method, especially in America.

In considering the value of blood transfusion in the treatment of disease, there are, in the first place, some general points to be mentioned before going into the indications for its use and attempting to estimate its

utility in various conditions. Like most remedies powerful for good, its employment may be attended by unpleasant or serious results, and this knowledge, combined with the difficulties of its technique in untrained hands, has necessarily tended to prevent its performance in acute cases, and to delay its adoption in chronic cases until the patient is past curative measures or even in *extremis*.

#### The Duration of Survival of the Transfused Blood in the Recipient's Circulation.

By the differential agglutination method Ashby determined that the transfused red cells persisted in the recipient's blood for thirty days or more, and that the period of survival is subject to much variation, the process of removal not being constant, but taking place in more or less cyclical crises; previous to this their life had been considered to be from ten to twenty-six days (W. Hunter, 1884). It might be anticipated that the duration would vary with the morbid condition of the recipient, and be shortened in haemolytic and toxic states, and longer in traumatic anaemia. But Ashby found that in four cases of pernicious anaemia the transfused cells survived as long as or longer than in persons without any blood disease. In contrast to this stability in pernicious anaemia was their rapid disappearance in myeloid leukaemia, aplastic anaemia, and haemolytic jaundice; Wearn, Warren, and Ames found that there was not any difference, as regards the survival of the erythrocytes, between pernicious and secondary anaemia, and that the average was 83 days, with 59 and 113 days as extremes. Jervell, also employing the differential agglutination method, found that in melaena neonatorum the duration was six weeks.

#### REACTIONS.

The incidence of post-transfusion reactions has been variously estimated, and probably the considerable divergences recorded depend on different views of what constitutes a reaction. Among 129 citrate transfusions Lewisohn observed a chill or fever up to 101° F. in 19 cases, or 15 per cent.; Souter and Duryea among 190 transfusions recorded subjective symptoms with or without fever in 49 cases, or 25.7 per cent.; Lindeman in 1914 met with an incidence of 33 per cent. out of 150, and in 1916, under improved conditions of technique, of 9 per cent. among 153 transfusions; Meleney, Stearnes, Fortune, and Ferry among 280 transfusions noted fever, over 100° F., in 178, or 63.6 per cent.; Kordenat and Smithies record only 4 per cent. of reactions in their 106 cases, but state that, if carefully observed, all transfusions are followed by a febrile rise of degree varying from 100° to 105° F. within three hours of the procedure. Their conception of a reaction would obviously greatly reduce the reported incidence of post-transfusional reactions.

**Etiology.**—Very severe reactions due to gross incompatibility, to air embolism, and pulmonary oedema, should be obviated by care in typing the blood of the donors and patients, and in technique; but reactions still occur, and it seems impossible to foretell when a reaction will or will not ensue. Presuming that the typing has been correctly done, it is conceivable that the blood groups are not so sharply marked off as they appear to be *in vitro*, and that transitions ("minor" agglutinations) or even changes occur, which are sufficient to cause haemic alterations and symptoms—in other words, that the tests *in vitro* are not sufficiently delicate to separate slight degrees of incompatibility *in vivo*. It is perhaps significant in this connexion that reactions are often seen, in spite of preliminary typing, in cases of pernicious anaemia in which, from the changes in the bone marrow, obscure alterations in the constituents of the blood may reasonably be anticipated. Indeed, in severe chronic anaemia it is occasionally difficult to find a suitable donor as the tests are not sharply defined (Thalhimer), and there is some evidence that in addition to the four recognized blood groups abnormal blood groups occur in certain conditions, such as pernicious anaemia, chronic haemolytic jaundice, and malignant disease (Keynes<sup>2</sup>; Kolmer; Jones and Glynn). It is remarkable that the decision as to the compatibility of the donor's and recipient's blood has been determined by the behaviour of the red blood corpuscles, and that the factor of possible changes in the leucocytes

and platelets has been almost entirely neglected. Doan has observed in some instances in which the bloods, as tested by the ordinary typing method, were compatible, that there was well marked destruction of the leucocytes, and that there was a greatly increased amount of cellular debris in the plasma, which distinguished it from the leucopenia of protein shock. In order to avoid reactions due to incompatibility between the blood plasma and the leucocytes, he advises and describes a method of testing for this before transfusion.

Reactions are more often seen after large transfusions than after small ones of 200 c.cm., and after repeated injections than after the first. But a fatal result has occurred after a single transfusion (Carrington and Lee). The addition of anticoagulating agents has been said to increase the incidence of reactions; thus Minot and Lee found reactions more frequent after citrated than whole blood in the proportion of 35 to 15; Unger (1917) febrile reactions in 60 per cent. of citrated transfusions as against 3.5 in 165 ordinary blood transfusions; and Lederer 49.5 per cent. reactions in 49 citrated infusions as against none in 40 transfusions of unaltered blood. Possibly the citrate renders the red cells more fragile (Unger, 1921), and so favours haemolysis. Keynes,<sup>44</sup> however, while admitting the possible influence of citrated transfusions in causing reactions, regards their occurrence as of little importance and as greatly outweighed by the advantages of the method.

*Influence of Repeated Transfusions.*—Many clinical observers (Keynes<sup>45</sup>; Bowcock; P. W. and M. C. Clough; Souter and Duryea) have noted that after repeated transfusions, from donors originally compatible, the patients are likely to show reactions, and it has been suggested that anaphylactic shock from sensitization of the patient had occurred, and that therefore it may be advisable to change the donor. In 1917 Libman and Ottenberg insisted that after repeated transfusions from the same donor agglutinins and haemolysins for the donor's red cells develop and that it is therefore essential to repeat the preliminary blood tests before each transfusion. Peyton Rous and Oswald Robertson have proved that in experimental rabbits repeated transfusions from donors originally compatible lead to the formation in the recipient of antibodies (iso-haemoagglutinins and haemolysins) which cause massive agglutination of the red cells and even fulminant haemolysis *in vivo* with resulting anaemia.

*Forms of Reactions.*—Kordenat and Smithies have described three kinds of reaction after transfusion: (1) Acute and fulminant response due to agglutination and haemolysis, coming on immediately. These should be prevented by careful preliminary typing of the donor's and recipient's bloods. (2) Delayed or proteolytic response coming on from one to twelve hours after transfusion, and ascribed to bacteriolysis or to protein cleavage of damaged tissues at an infective focus, and not to haemolysis. This reaction is regarded rather in the light of a conservative process, inasmuch as the recipients are often benefited by it—just, indeed, as they are after protein shock therapy; death, however, is not unknown. (3) Systemic or constitutional reactions which, like the last group, are not haemolytic as there is not any evidence of blood destruction. The explanation of these frequent febrile reactions is obscure; Kordenat and Smithies again mention bacteriolysis and proteolysis, and also suggest that the reactions are analogous to protein shock and not necessarily specific. Lindeman (1916), however, argues that they are due to haemolysis occurring in the body, but not shown by the preliminary tests or, unless considerable, by haemoglobinuria or porphyrinuria; he compares it with the fever and rigor in malaria after haemolysis, and quotes some experiments showing that fever is produced by the injection of haemoglobin. There is, however, little clinical evidence that haemolysis alone does much harm; for example, in congenital haemolytic jaundice in which, though icterus is more obvious than in the minor reactions after blood transfusion, there is little in the way of acute symptoms; Karsner, while pointing out the lack of proof that haemolysis alone is responsible for these reactions, admits the possibility that accompanying the haemolytic process toxins capable of causing serious results may be

formed. Melency, Stearnes, Fortuino, and Ferry, by examination of the urine for urobilin and haemoglobin, failed to find any constant evidence of such haemolysis, and therefore could not accept this explanation for all the cases. Sodium citrate in citrated blood has been thought, either by causing haemolysis or independently, to be responsible for reactions. Other conceivable causes are similar occult agglutination of the transfused erythrocytes—although the preliminary tests did not show it—damage to the red cells or changes in the plasma protein during the process of transfusion, the formation of toxic split-protein, agglutination of the leucocytes, and changes in the platelets associated with incipient coagulation (P. W. and M. C. Clough). It is, of course, possible that these minor post-transfusion reactions may be due to different factors in different cases.

#### THE WAYS IN WHICH BLOOD TRANSFUSION MAY BE THOUGHT TO DO GOOD.

In emergencies it may merely make good the deficiency of the blood after acute haemorrhage, such as post-partum or traumatic, and some of the best results in the way of saving life have been obtained in such cases of haemorrhagic shock. The fear that by increasing the arterial pressure it may induce bleeding from the original source of haemorrhage (I. Bennett) is perhaps more than counterbalanced by the increased coagulability of the blood. In four observations Eyster and Middleton found that the rise in arterial pressure was slight and transient, the maximum being 20 mm. Hg in both the systolic and diastolic pressures.

In recurrent or chronic haemorrhage it may act as a styptic by supplying fibrinogen and thereby increasing the coagulability of the blood. But here its effect is palliative rather than curative, as the underlying cause is not removed.

In chronic anaemia, by supplying the deficiency of red-blood corpuscles. Here the problem is not so simple as in acute haemorrhage, for the etiological factors, such as infection, malignant disease, and disorder of the blood-forming organs, persist and must be taken into account. It may, however, enable a very anaemic patient, who otherwise could not, to stand an operation for the removal of the underlying cause of the anaemia, such as bleeding uterine fibromyomas (Williamson); in such cases transfusion may be done both before and during the operation.

To supply substances in which the blood is deficient, such as antibodies in acute infections and functionally active haemoglobin as in CO poisoning in which it is fixed by the CO.

To act on the bone marrow. In disordered conditions, such as leukaemia, it might, by supplying it with healthy blood, correct the disturbed functional activity, for it is obvious that the bone marrow must be efficiently nourished if it is to discharge its function in a normal manner. In chronic anaemia, especially pernicious or Addisonian anaemia, transfusion is often said to act by stimulating the bone marrow, because the improvement may be out of proportion to the amount of blood transfused; Hurst, indeed, suggests that healthy blood contains a hormone which specifically stimulates the bone marrow, and also that it may contain antibodies. On the other hand, loss of blood is in itself a stimulant, haemoglobin has not been proved to stimulate the bone marrow, and stimulation pure and simple might be thought to be harmful by tending to exhaust an already overworked bone marrow, as in ordinary pernicious anaemia. Theoretically it might also appear likely to be more useful in some of the cases grouped under the heading of aplastic anaemia, in which the bone marrow is paralysed by some "brutal" infection or toxic factor, such as benzol, than in ordinary pernicious anaemia, in which the bone marrow is already hyperplastic; but in benzol poisoning the results of transfusion have been very disappointing according to McClure, who, however, reports one cure. It has been suggested that the transfused cells give the bone marrow a rest, after which it is able to respond to the stimulus, which previously it could not do (Opitz; Isaacs), and also that transfusion provides sufficient oxyhaemoglobin to enable the hyperplastic bone marrow, which had been comparatively

inactive on account of its poor blood supply, to manufacture the necessary quantum of red cells (Ryffel).

To remedy toxæmia. In acute hæmorrhage it has been stated that death is due to toxæmia from imperfect destruction of toxic products rather than to the diminution in the quantity of blood (Bätzner), and there is evidence that hæmorrhage is followed by increased nitrogenous metabolism, and blood transfusion by a return towards the normal; fresh blood might also facilitate destruction of these toxic bodies. Dilution of the blood in grave toxæmia by transfusion would have the theoretical advantage that the dilution would not be so rapidly diminished by the passage of blood plasma into the tissues as occurs in saline transfusion, in such cases a preliminary venesection is theoretically advisable.

In bacterial septicæmia. Healthy whole blood has bactericidal properties in virtue of the leucocytes acting in conjunction with the opsonic power of the serum, the serum having little direct effect (Wright, Colebrook, and Storer).

#### THE INDICATIONS FOR BLOOD TRANSFUSION.

These have been based on the general grounds of the degree of anaemia present, such as a fall to one million red blood corpuscles and 20 per cent. of hæmoglobin, and on evidence of hæmorrhage to 2,000 c.cm. with a systolic pressure falling below 80 mm. Hg, or according to the morbid conditions and diseases, lists of which regarded as suitable for transfusion have been drawn up by various workers. Dorrance gives twelve separate groups of diseases, Libman and Ottenberg (1917) seven categories; Keynes's<sup>42</sup> four inclusive groups are (1) acute hæmorrhage and anaemia; (2) chronic anaemia, to tide a patient over an operation or to benefit the condition, prolong life, and in the hope of cure, as in Addisonian anaemia; (3) in hæmorrhagic diseases; and (4) in general toxæmia, bacterial or chemical. That absolute contraindications exist has not been satisfactorily established. In a patient apparently moribund from acute hæmorrhagic anaemia transfusion may perform a miraculous transformation; in chronic anaemic states in which the underlying condition persists the circumstances are different, and in pernicious anaemia a stage may be reached when harm rather than benefit is likely to follow transfusion. Libman and Ottenberg (1917) very cautiously suggest that pneumonia or pulmonary congestion may be a contraindication, and mention an almost fatal febrile reaction (107° F.) in a child with pneumonia transfused for anaemia; but according to Bass this does not apply to pneumonia in anaemic infants. From the toxic effects of citrates on the kidneys the use of citrated blood in nephritis demands caution.

Acute anaemia due to hæmorrhage is most successfully treated by blood transfusion and is a life-saving procedure, as was proved in the war, for traumatic hæmorrhage; its value in post-partum hæmorrhage and ruptured ectopic gestation is also acknowledged. In ruptured ectopic gestation the blood free in the peritoneal cavity has been utilized for transfusion, and in this way time spent in obtaining and testing a donor is saved; Blain and Brines, however, deprecate such retransfusion from abdominal hæmorrhage. It restores the blood volume and provides the oxygen-carrying hæmoglobin. A distinction between shock, in which gum solution has been advocated (Meakins) on the ground that both the blood volume and the hæmoglobin are probably increased, and hæmorrhage may be difficult to determine, and Keynes<sup>42</sup> advises blood transfusion in both.

In gastro-intestinal hæmorrhage Izod Bennett disapproves of blood transfusion as it may excite fresh bleeding from an ulcer which had ceased to bleed as a result of the lowered blood pressure, and he approves of it only during laparotomy. Keynes, however, takes the opposite view. In addition it has been suggested that it may accelerate healing of a peptic ulcer by Horder (1923), who has also seen improvement in ulcerative colitis; in 1908 Hort advocated the treatment of ulcers by horse serum, which he believed favoured healing by its antiautolytic action. Usually large transfusions (1,000 c.cm.) have been given, but W. J. Mayo has advocated the superiority of small repeated transfusions over a single one. Citrated transfusions are largely employed, and as the object is to

provide fresh red blood corpuscles and increase the blood volume, the question of the citrate impairing the bactericidal power of the blood does not arise.

In chronic anaemia due to repeated hæmorrhages and in debility blood transfusion, in order to render feasible an operation for removal or remedy of the cause, has been employed with gratifying results, especially in gynaecological cases (Souter and Duryea; Williamson), and also in gastro-intestinal hæmorrhage. In these cases it may be necessary to repeat transfusion during and after the operation. When the condition is not urgent Libman and Ottenberg recommend an interval of two days between the preliminary transfusion and operation.

As a prophylactic against post-operative shock transfusion has been much employed; Blain and Brines adopt this course in nearly all their goitre cases, and in infants with pyloric stenosis it has reduced the mortality (Cross).

In hæmorrhagic diseases and conditions with the loss of blood so continuous or repeated as to become serious, transfusion is useful by supplying the missing thrombogenic factors, such as the blood platelets in purpura hæmorrhagica. Paradoxical as it may appear, the addition of sodium citrate as an anticoagulant does not interfere with the hæmostatic effect of the blood transfusion.

Purpura hæmorrhagica is characterized by bleeding from mucous surfaces, a diminution in the number of blood platelets from the normal 250,000 to 40,000, 5,000, or even less, in the shed blood (thrombocytopenic purpura), a prolonged bleeding time often exceeding two hours (Dukes), but often no abnormality in the coagulation time. Though thrombocytopenia is usually regarded as confined to purpura hæmorrhagica and to be one of its essential features, this has been vigorously denied by Tidy. Blood transfusion, which had sometimes to be repeated, as the life of the platelets is said to be four days only, was formerly the chief form of treatment, but recently splenectomy has come into vogue, and has been found to give more uniformly successful results (Vincent<sup>77</sup>); Poynton, Thursfield, and Paterson regard transfusion as dangerous, but Tidy recommends transfusion before splenectomy.

In hæmorrhagic disease of the newborn, *melaena neonatorum*, the performance of blood transfusion presents technical difficulties, unless the superior longitudinal sinus, the external jugular, or the umbilical vein (Sidbury) be utilized. Citrated blood exerts a styptic effect, and according to Torii is the simplest and safest method; whole blood has been given hypodermically. In most cases a single transfusion is sufficient. Very encouraging reports of its efficacy have been made by Vincent,<sup>78</sup> who had four deaths only among thirty-one cases, and by others (Laurie; B. Robertson; F. W. Robertson; Eyres), and it not only arrests bleeding but augments the depleted circulating blood.

*Hæmophilia*.—Although the blood platelets are never diminished in this disease, the hæmostatic effect of the blood transfusion is ascribed to the supply of blood platelets, and as their life is about four days this influence is short. Minot and Lee's experience is that, in order to supply a sufficient number of platelets, fairly large transfusions are desirable; Keynes,<sup>42</sup> on the other hand, states that 100 c.cm. is sufficient for the hæmostatic effect. It is useful both as a prophylactic to prevent bleeding during a necessary operation and to arrest hæmorrhage from slight injury; as its effect is transient further transfusions may be required, especially during the healing of a wound. In the severe anaemia due to loss of blood transfusion also does good service.

*Jaundice*.—From the prolonged coagulation time and tendency to bleed which, from the general oozing, becomes such a serious factor in operations on deeply jaundiced patients, blood transfusion appears to be the most effective prophylactic, but is not constantly successful and its effect is transitory. In some cases of deep jaundice the coagulation time is not abnormal and bleeding does not occur; as the coagulation time can sometimes be made normal by the administration of calcium, estimation of the coagulation time will determine whether or not blood transfusion is necessary. Recovery in grave familial jaundice of the newly born has followed venesection and transfusion (Hart). Its employment in chronic hæmolytic jaundice is open to

discussion, as it is hardly likely to effect more than temporary benefit; but it may be of value in connexion with splenectomy.

**Pernicious Anaemia.**—The value of blood transfusion in Addisonian or pernicious anaemia has been very variously estimated, and the irregular course of the disease and the tendency to spontaneous remissions make judgement difficult. Some regard it as undoubtedly of great value (Keynes<sup>42</sup>; Anders; Stetson; Hurst), others as merely a means of obtaining temporary improvement (Panton), and others as so inefficient and dangerous that they have abandoned it (Landis). It has been definitely stated to bring on a remission, though the remissions are not thereby prolonged. In Anders's collection of 362 cases a remission was initiated in 204, or 56.3 per cent. Libman and Ottenberg regard it as the best remedy for, but never curing, the disease, and Bloomfield, from an analysis of 57 cases, agrees that in patients who are not in a condition refractory to all forms of treatment transfusion is more often followed by a remission, but that the remission is not thereby lengthened or life prolonged. Recent acute cases seldom respond to transfusion; cases without remissions are rarely benefited, and patients over 60 years of age often fail to show improvement (Archibald). Chronic cases with remissions are more likely to benefit. Transfusion should be employed in early and not left to late stages, when not only may it fail to bring about a remission, but it may be followed by a serious reaction and even death. Small (200 to 500 c.cm.) rather than large transfusions seem to be more suitable, and are often repeated frequently; in 1924 Hurst reported very promising results from 20 to 25 c.cm. injected on every other day. It has been suggested that if benefit does not result from a transfusion another donor should be utilized; the change of donor has also been recommended in order to avoid anaphylactoid shock. As already mentioned, reactions are rather frequently noticed in pernicious anaemia; after repeated transfusions from the same donor, especially when there is an interval of three to six weeks between the first and a second transfusion, the reaction has naturally been regarded as anaphylactic (Böttner). Transfusions which are followed by improvement have been found to produce a fall in the amount of bilirubin in the plasma, either immediately, or gradually during two or more weeks (Broun, Ames, Warren, and Peabody).

Reed and Wyckoff, who, like Hurst, regard subacute combined degeneration of the cord as closely allied, add sprue to this group and recommend transfusions.

In their category of *anaemia gravis* of children Poynton, Thursfield, and Paterson include not only cases commonly labelled "aplastic anaemia," but others; as a whole these cases are regarded as occupying in children's diseases the place of, though presenting many differences from, pernicious anaemia in adults. In this condition transfusion is regarded as dangerous.

**Anaemias other than Addisonian.**—Infantile splenic anaemia, or von Jaksch's anaemia pseudo-leukaemia infantum, has a tendency to undergo spontaneous cure, Thursfield putting the recovery rate at 65 to 70 per cent. In this condition transfusion has been said to have a more dramatic and lasting effect than in any disease of children (Bourne). In acute febrile anaemia, described as a new disease by Brill, who refers to two other cases (Macintosh and Cleland; Moschowitz), there is pleiochromic anaemia with hyaline thrombosis of the terminal arteries and capillaries. In Brill's patient, who had one million reds, 5,000 leucocytes (polymorphonuclears 61, lymphocytes 36, eosinophils 2), and blood sterile on culture, recovery followed ten transfusions of 300 to 500 c.cm. of blood.

**Leukaemia** is due to a riotous growth in the leucoblastic tissues, mainly of the bone marrow, and discussion whether or not it should be regarded as allied to sarcoma or infection has lost much of its point in the light of Gye and Barnard's description of a cancer parasite. Transfusion has been employed with two objects: (1) symptomatically to stop haemorrhages, and (2) in the hope of exerting a curative influence.

(1) To prevent haemorrhages. In three cases of acute leukaemia Libman and Ottenberg (1915) failed to obtain any positive result, but in one chronic case transfusion was followed by cessation of the haemorrhages.

(2) The attempt to correct the morbid process in the leucocyte-producing tissues by providing normal blood, or by stimulating them in the right direction, or by supplying a hypothetical antibody, is justifiable in such a desperate disease, and in a few instances has appeared to exert a beneficial effect. There is very little evidence that acute leukaemia is benefited by blood transfusion; in an interesting case of microlymphoidocytic leukaemia lasting four months twelve blood transfusions probably prolonged the course of an illness which is usually of very short duration (Fineman). In chronic leukaemia, in which the course is not so steadily downhill, there may appear to be more in the way of results from transfusion. Thus out of five cases of chronic lymphoid leukaemia given one transfusion by Libman and Ottenberg (1915) four showed clinical improvement and a remarkable blood change, the picture becoming normal for a week to a year. Dr. Herbert French tells me that repeated transfusions certainly improve the patients, especially when they are started early in the course of the disease.

**Acute Septicaemias.**—The general opinion is adverse to blood transfusion in acute haemic infections, as they fail to benefit, and may do harm from the formation of abnormal agglutinins and haemolysins. Eardley Holland has abandoned it in acute puerperal infections. It has been thought that transfusion may increase the patient's general resistance, possibly because the blood may happen to contain specific antibodies, as in a donor who has recently recovered from the same disease, a condition which is imitated in Wright's immuno-transfusion, when a donor is specially immunized against the patient's infection. According to Colebrook and Storer the bactericidal properties of whole blood for streptococci and staphylococci are impaired by the addition of citrates, and therefore citrated blood should not be employed in immuno-transfusion. Walsh and Harmsworth, while confirming Colebrook and Storer's conclusion that defibrinated blood is superior in bactericidal power to citrated blood, find that the bactericidal power of the blood is enormously increased by coagulation, that citrates inhibit the growth of staphylococci in the blood, and that citrated defibrinated blood has a greater bactericidal power than defibrinated blood. With unmodified blood Stetson obtained cures in 31 out of 57 cases, and reported 10 recoveries out of 19 cases of *Streptococcus haemolyticus* infection; he insists on the importance of early and repeated transfusions. Immuno-transfusion proved successful in cases of streptococcal septicaemia reported by Fry in 1920. In malignant endocarditis Libman and Ottenberg (1917) obtained brilliant temporary results, but the 7 cases reported by Stetson all proved fatal. Horder (1926), though critical, considers it worth a trial, as improvement sometimes occurs, and appears to think better of it than of immuno-transfusion, which, however, has in exceptional instances been followed by recovery (Wordley). Thayer treated a case of streptococcal endocarditis for six months by repeated immuno-transfusions, but although the result did not appear superior to that of simple transfusion, he considers it worthy of further trial, and no doubt it is still in a stage awaiting final decision.

In chronic infections it has been employed with benefit in various conditions (Nathan; Brown; Hansen).

**Intoxications.**—In carbon monoxide poisoning the introduction of functionally active red cells to carry oxygen while the recipient's haemoglobin is fixed by CO has been long advocated and supported by experimental observations. (Burmeister). A preliminary venesection has been recommended, and with this proviso Libman and Ottenberg (1917) spoke highly of it. J. S. Haldane, however, cannot see any scientific reason for the employment of preliminary venesection or for transfusion of blood. In illuminating gas poisoning other toxic factors may be concerned, and it has been thought that this may justify venesection.

In uraemia and diabetic coma blood transfusion has rarely been performed, and in diabetic coma insulin is, of course, the proper treatment. Blair Bell obtained a cure in puerperal eclampsia after one blood transfusion of 500 c.cm. Blood transfusion has been regarded as the best diuretic in oliguria with impending anuria (Martin); in a case of anuria following decapsulation for acute

nephritis recovery followed venesection and transfusion (Bowers and Trattner). Cross found it beneficial in intestinal toxæmia and in that following burns in children.

**Debility.**—In premature and congenitally weak infants who lose weight in spite of proper care, Guéniot obtained good results by transfusion of 10 to 20 c.cm. into the superior longitudinal sinus. Cross confirmed these good results in debilitated infants. In patients who, without any obvious cause, hang fire after operation, Brines found that improvement followed transfusion.

## II.—G. LOVELL GULLAND, C.M.G., M.D., F.R.C.P.E.,

Professor of Medicine and Clinical Medicine in the University of Edinburgh; Senior Physician to the Royal Infirmary, Edinburgh.

I HAVE been practising transfusion or seeing it practised for over thirty years, mainly in pernicious anaemia, but of late years in other conditions with increasing frequency, and have reached definite conclusions as to its value in several of these. I cannot help thinking that the duration of survival of the transfused corpuscles is overstated by the American and Scandinavian authors quoted by Sir Humphry Rolleston. There are many possibilities of fallacy in the differential agglutination method—we inject many other things besides the corpuscles in transfusion—and in transfused cases which do not do well, even though there is no haemolysis, and even in some which ultimately do well, the blood counts after transfusion do not bear out the view that the corpuscles survive so long. The rule is to find an increase of corpuscles, but it is exceptional in the type of case of which I am speaking for the increase to be maintained for more than a few days. The count then drops back to its previous level, or below it if the case is doing badly, and it is, I think, permissible to conclude that the transfused corpuscles have largely disappeared from the circulation. I have followed these cases many times by daily counts, and daily examination of films, in the hope that I might be able to recognize some at least of the transfused corpuscles, or make out some change in the blood picture as the result of the transfusion. The transfused corpuscles are never recognizable; I think because there are, even in the worst pernicious anaemias, a sufficient number of corpuscles of normal appearance to mask the new ones, and the blood picture as a whole only changes if the disease is getting worse or better in the ordinary course.

I am impressed, in looking back on my earlier cases, by the luck which I seem to have had in escaping reactions in the days before blood grouping was known. I can recall only two, neither fatal, out of a large number of cases. I have not always been so fortunate of late, even when the grouping was most carefully done. A few days ago a patient suffering from carcinoma of the stomach, who was very anaemic, was transfused, with a view to operation, from a source which was apparently absolutely compatible. There was a fairly severe reaction with marked haemoglobinuria, and, as far as I could judge from the count, a complete loss of the transfused corpuscles. Not long ago I had a very severe reaction, threatening death, in a pernicious anaemia during transfusion with a blood which I had satisfied myself was compatible. In a sense I was prepared for trouble in this particular case, as I have never seen anyone who was so intolerant of drugs and remedies of every kind. He lived for about a year after the transfusion and gave me a useful lesson on the ups and downs of an untreated case. I have passed through all the various fashions in the methods of transfusion, whole blood and the various anti-coagulants, and, so far as the effect on the patient is concerned, I do not think there is any great difference. The citrate method is certainly the easiest for the donor and the operator. Probably I should have used transfusion even more often than I have were it not for the difficulty of getting suitable donors. I am under a deep debt of gratitude to a patient suffering from a polycythaemia who has many times given her blood for my cases. She is fortunately a universal donor, and her corpuscles have done good to many, abnormal though they may be in themselves, while the repeated bleedings have kept her in much better health

than she was previously. Following her example another patient with polycythaemia, a male and also a universal donor, has begun a useful career in that direction.

Sir Humphry's discussion of the ways in which transfusion may do good is excellent, and I have nothing to add to it from the general point of view. But I should like to consider more fully the case of pernicious anaemia. It is now so common a disease that the consideration of transfusion must come up frequently to every physician. My own experience has convinced me that arsenic given by the mouth is so immensely superior to all the other methods of treatment put together that every case should have a proper trial of that remedy; and, further, that cases that will not do with arsenic by the mouth will seldom respond to arsenic given in any other way or to any other form of treatment. I have seen many cases, apparently desperate, respond brilliantly to arsenic—of course conjoined with rest, proper diet, and nursing, and the treatment of their individual symptoms. I am always inclined, therefore, to try this first, though sometimes the cases are so bad that it is obvious that time is an important factor, and we are driven to a transfusion at once, generally with a justification of the bad prognosis already given. The blood count is always to be considered. A patient with a red count of 1,000,000 cells per c.mm., and a haemoglobin percentage of, say 25, is not in immediate danger from the anaemia. His declension to that level has been gradual, and he is in a very different case from the patient whose count has fallen suddenly to that figure as the result of haemorrhage. In the first case the organs have become accustomed to their anaemia; the patient may be in danger from his heart, his kidneys, his alimentary tract, or from intercurrent disease, but if these do not affect him specially, there is time for treatment with arsenic. Cases with evidence of cardiac failure, with chronic kidney mischief—which is much more common in pernicious anaemia than is usually recognized—with marked fever, whether apparently causeless or due to some complication, and patients with severe hepatic or gastric disturbance, are not good cases for transfusion.

Here I may interpolate a little theory. Pernicious anaemia is a toxæmia, caused by various poisons, which, so far as the bone marrow is concerned, have the common effect of interfering with the normal normoblastic reproduction of red corpuscles so that it passes more or less completely, but never entirely, into abeyance, and the marrow falls back on the megaloblasts for blood production. All, or at any rate most, of these toxins act in a cyclic manner, producing anaemia at first gradually, then more rapidly, but at last either exhausting themselves or producing antibodies which counteract them. When this point is reached, if the patient has sufficient vigour the normoblastic function resumes its work and reproduces a more or less normal blood, sometimes with astonishing rapidity, sometimes more slowly. If the source of the toxæmia is not removed the cycle may be repeated on several occasions. Very few patients come under competent observation until their blood has run down to a low level, and in many cases, though not in all, we cannot stop the process of declension by transfusion or anything else until the toxic process is exhausted. In every case the question which has to be answered is, "Can the patient live long enough to overcome or exhaust the toxin, and has he sufficient vigour to recover a normal blood-formation when the toxic process is over?" In no two cases is the answer to that question arrived at in the same way, for it depends on previous history, duration of the disease, presence or absence of general or special degenerative change, and so on, in addition to the actual blood picture and the symptoms of the disease itself. The great majority of cases of pernicious anaemia recover from their first attack, with or without treatment, and often in spite of wrong treatment. It is only in cases of exceptional severity that transfusion has to be considered in a first attack; usually it is in second, third, or even fourth attacks that it is considered and used. Its real value is to help the patient round the critical corner, to raise his low vitality, exhausted by toxæmia, and give him a chance to recover himself. It is not curative in the sense in which arsenic is curative. The transfused blood may

contain antibodies, but as it is not known what the toxins are which cause pernicious anaemia, it is mere chance whether the antibodies injected are in any way related to the toxins. It is, indeed, improbable that they will be, for we try to select as donors young healthy people who are not likely to carry the antibodies required by the older degenerated people who are the usual subjects of pernicious anaemia. The supply of healthy corpuscles and healthy plasma must be of value, and while there is in a sense no object in stimulating a marrow which is already hyperplastic, it is to be remembered that the hyperplasia is one of megaloblasts and not of normoblasts, and that it is quite possible that the healthy blood may stimulate the more or less dormant normoblasts and enable them to start proliferating afresh. It is much to be regretted that we know nothing of the condition of the marrow in the remission stage—we do not know whether the hyperplasia of megaloblasts disappears or not; when patients with pernicious anaemia die in the stage of remission, as they do occasionally, it is practically always when they are out of observation.

To sum up, transfusion is most useful, in my experience, in uncomplicated cases which are lagging, and failing to raise their blood count by their own and our efforts. If we had an unlimited supply of donors it might be worth while to transfuse every case when it first comes under observation, but I doubt very much whether results would be any better than at present. If a patient does not respond to one transfusion, a second will rarely help him. I remember one case in which the patient turned the corner with a transfusion, and went away, comparatively well, to another city. He and his friends were so much impressed by the result that they insisted on repeated transfusions at short intervals, until the blood was pushed up to normal, with the unfortunate result that his heart apparently could not stand the strain of repeated transfusion, and he died of cardiac failure.

The value of transfusion in acute haemorrhage and before and during operation is so well established that I need not emphasize it. In leukaemia it is necessary to distinguish sharply between the acute and chronic forms. At one time I treated several acute leukaemias in succession by transfusion. In no case was there any improvement, either clinically or in the blood picture, though there were no severe reactions; the course of the disease did not seem to me to be altered in any way, and I have not used the method recently in these cases. In the chronic leukaemias, granular and non-granular, the only indication I have adopted for transfusion has been intractable haemorrhage which would not respond to other treatment, and I have twice had good results. I am doubtful whether transfusion in the ordinary course is likely to give such good results as radiation.

In aplastic anaemia, owing to the hopelessness and inefficacy of every other form of treatment, we are sometimes driven to a transfusion. But it is never of any service in the acute forms, and sometimes causes sharp reactions; in the more chronic forms, in which I have sometimes transfused repeatedly, there was no effect beyond the short and temporary relief from the increased number of corpuscles.

During the past year my attention has been specially drawn to haemophilia. The starting-point was the admission to the ward of a haemophilic in whom the removal of several teeth had become urgent. This led to the study of the effect on his coagulation curve of all the substances reputed to be useful, and ultimately to the bringing into the ward of all the haemophiliacs and suspected haemophiliacs that could be found. I do not propose to foreshadow the results of this study—it would take too long to do so; it must suffice to state that transfusion was found to bring the coagulation curve nearer to the normal, and to do so more rapidly than any other method, while repeated transfusions seemed to start the patients off on a higher plane of health and resistance.

I have not yet made up my mind about the value of transfusion in purpura haemorrhagica. Some cases have done well with it, and have had no recurrence for long periods, but I have a patient at the moment who was transfused in the beginning of May. The haemorrhages

ceased and there was a definite improvement in the blood, but during this month the bleeding started again, and I propose now to give him a preliminary transfusion and then to give a large quantity during the course of a splenectomy. I have seen no bad results from transfusion in this condition.

Transfusion, if it is used discreetly, is certainly one of the most valuable remedies in a number of diseases, and is sometimes the only one which will save our patients.

### III.—RENE CRUCHET, M.D.,

Professor of Pathology and General Therapeutics in the University of Bordeaux.

#### TRANSFUSION OF BLOOD FROM ANIMAL TO MAN.

##### *General Considerations.*

It is difficult to speak about transfusion of blood without recalling the name of Harvey, whose well known book on the circulation of blood, published in 1628, inspired by this immortal discovery therapeutic hope till then unimagined. Harvey made for the first time this fundamental observation: "It is evident that the principle of contagion which has reached part of the body has gone back to the heart with the circulation of the blood, and can from there infest all the body."

If the circulation explains the disease, it can also explain the remedy. From this sprang Harvey's other remark: "Is it not reasonable to say that the veins absorb the substances and introduce them in the blood?"

Thus some bold experimenters, such as the English scientists Christopher Wren, Boyle, and Clarke, between 1656 and 1660 injected into the veins of animals, and even human beings, opium, milk, and broth; it was the so-called "infusory surgery." But when they began to think about injecting medicines, they would naturally also have been expected to think of injecting blood: it was the "transfusory surgery." At first it was the transfusion between animals of the same species, then of different ones. Let us specially note the memorable experiments at Oxford in 1666, made by Richard Lower from dog to dog, and those of Edmund King and Thomas Coxie in 1667 from calf to sheep. These experiments having fully succeeded, the method was tried on men, and honour is due to the Frenchman, Denys of Montpelier, in 1667, who, the first in Paris, employed it in four human subjects. The successes obtained were remarkable; they showed in the most convincing way that the transfusion of lamb's or calf's blood to man was possible, as Richard Lower and Edmund King proved in the same year with full success.

Notwithstanding, transfusion was soon forgotten, and it may be said that no more attention was paid to it, apart from some interesting experiments, till about 1860. At that time Dr. Oré, professor of physiology at the School of Medicine of Bordeaux, began a series of remarkable studies on this subject, which he pursued all his life; they are published in his work, which became classical, and of which the second edition was published in 1876.

Oré, defender of the transfusion from animal to man, was able to show by experiments and with precise statistics that this way of transfusing blood was superior to man-to-man transfusion. Notwithstanding, the transfusion from animal to man, as from man to man, was still beset with practical difficulties, and accidents were too frequent. The most favourable statistics, in the method of animal to man, gave more than 16 per cent. fatalities, which was not at all encouraging; moreover, the reactions provoked by transfusion were often very acute: rigor, pyrexia, acceleration of the pulse, dyspnoea, sweating, lumbar pains, haematuria, headache, vomiting, and collapse.

Asepsis and antisepsis being unknown at that time, it was necessary also to take into account quick coagulation of the blood, which, as Oré had observed, might cause embolism.

It was only in 1917 that, following the works of Hédon and Jeanbrau of Montpellier, Agote (Buenos Aires), and Lewisohn (United States), it was found possible to stop the blood from coagulating by sodium citrate, rendering it possible for transfusion to be adopted practically. In the

meantime, after Pasteur's and Lister's work, surgery had been completely transformed.

##### *Clinical Observations and Results.*

The moment seemed to have come to take up again, on a modern basis, the ideas of Oré—the transfusion of blood from animal to man. We have undertaken this study since 1921, and here are the results. We began by making numerous experiments of the transfusion of blood between animals of different species. We established that it was possible, without accident, to inject into dogs the citrated blood of sheep, ox, or horse in considerable amounts, proportional to the weight of the animal—100, 200, 300, and even 400 c.cm., which represent transfusions equal to two and three litres of blood for a man.

Encouraged by these observations, we then carried out the transfusion of the blood of sheep and horse to man, but in small doses.\* Blood was taken with aseptic precautions from the animal at the level of the jugular vein and received directly, either in a big glass syringe or in the apparatus of Jeanbrau, the two receivers having previously been filled with 10 per cent. sodium citrate solution (1 c.cm. for 100 c.cm. of blood). The blood was immediately injected into a vein of the arm of the treated patients. The quantity has varied between 25 and 40 c.cm. of citrated blood; once we went up to 80 c.cm. of sheep's blood. The transfusion was always conducted slowly (lasting about two to four minutes in the first cases, but still more slowly in the later ones).

Injections of sheep's blood have been given to eight patients (four tuberculous, one hemiplegic, one anaemic, one asthenic, one encephalitic); it has been repeated once in two cases, which brings the total to ten transfusions.

Transfusions of horse's blood have been used for twelve patients (nine tuberculous people, one insane, one septicæmic, one pyæmic); two of these received two injections, which brings the number of transfusions made to fourteen.

These transfusions of blood from the sheep or horse provoke very often the following reactions: pains in the loins (the most frequent phenomenon, 16 times in 24 cases), acute pain in the loins, "waist pains" radiating to the pubis, bladder, and abdomen, and provoking sometimes micturition and evacuation. Twice there was vomiting. More infrequently rigors were observed, often slight, but sometimes violent, with shivering and dyspnoea, followed by sensations of heat and abundant perspirations, a slight elevation of temperature, with parallel acceleration of the pulse. Twice we observed slight fall of temperature with lessening of the arterial tension; in two cases headache occurred. These different phenomena disappear quickly in about a quarter to half an hour.

Twice the urine was red and the reaction of Meyer positive (presence of haemoglobin without red cells). Three times urobilin was found. The presence of albumin in small amount (0.1 to 0.2 gram per litre) is common. These urinary changes disappear in twenty-four hours. In two cases we have observed nettle-rash. The examinations of the blood and leucocytes in the transfused patient have given us contradictory results; but most frequently there is an increase in the number of the red cells and leucocytes after the transfusion.

Once in a case of pyæmia—considered desperate, it is true—sudden death followed the introduction of 1 to 2 c.cm. of the blood of a horse. Except in this case and in two others which remained unchanged, the state of our patients improved, and they have even asked urgently for repeated transfusion.

These results seemed to us most interesting; they show in the most evident way that the transfusion of blood from animal to man is possible with modern methods without bringing on more accidents than transfusion from man to man. It is clear that the small accidents which we have observed are exactly identical with those which we have seen in the transfusion of human blood, in the course of which sudden death may occur.

\* These are our first results, communicated to the Medical Congress of the Royal Institute of Public Health at Plymouth, June 2nd, 1922 (*Lancet*, July 15th, 1922, p. 140). Cruchet and Ragot, *Paris Medical*, January 27th, 1923, pp. 82, 85; Ragot, *Thèse de Bordeaux*, December, 1922.

But cannot these accidents, slight and temporary as they are, be avoided? That is what we have studied in the second part of our investigations.

#### Essentials in Correct Transfusion.

The great number of experiments which we made led us to the conclusion that bad technique was the usual cause of accidents in transfusion. The error is the too rapid transfusion, especially at the beginning of the operation. Here are the results of our observations.<sup>1</sup>

1. Whether the transfused subjects receive homologous or heterologous blood, the reactions seem exactly the same, and depend upon the rapidity of the flow.

2. The rapidity of the flow of the blood must be closely watched, if immediate or remote accidents, described long ago as occurring in transfusion, are to be avoided.

3. It is principally the flow of the first cubic centimetres which must be narrowly observed; for in the course of the transfusion the flow can be increased without resulting in any accidents. The flow goes on, following the oscillations of which we have established the curve.

4. This curve is divided into three successive periods, as can be distinguished in the following experiment: a dog of 13 kilos in which is transfused 260 c.cm. of a mixture of equal parts of citrated horse's blood and of physiological serum.

centimetre a minute when paraffin oil is used. These figures have not an absolute value, for they are governed chiefly by the curve already mentioned. The following curve, established for an infusion of gum arabic containing 90 grams in 1,000 c.cm. of physiological serum, is particularly typical.

7. Practically, it is enough to place the liquid to be transfused in a receiver on a level hardly higher than the heart of the patient who is to receive it. The essential condition of a good transfusion is that the heart of the receiver shall rule the flow, as is the case usually in the intravenous injections of physiological serum.

#### Other Factors in Transfusion Accidents.

Under the above conditions no accidents occur after transfusion, and the phenomena of agglutination, embolism, and haemolysis, so often incriminated in those accidents, do not seem to play an obvious part.

#### (a) Agglutination.<sup>2</sup>

Contrary to the classical view, mixtures of heterologous bloods do not necessarily produce agglutination. Thus, mixture of the blood of a guinea-pig or the blood of a horse with human blood can be performed very well without causing any accident. On the other hand, it is well to be aware that agglutination can occur, even strongly, without causing the smallest accident. The numerous transfusions of horse's blood we have given to the dog have always been without any danger, in spite of a positive agglutination, assuming, of course, that respect is paid to the laws of the rate of the flow already mentioned.

It is surprising, nevertheless, to think of the importance attached to this question of agglutination by modern advances in knowledge concerning incompatible bloods and blood groups, when we consider the numerous injections of different substances and serums introduced into the veins which lead, after all, to agglutination. We have shown, with Ragot, that arsenic ionoide, collargol, colloidal gold, and collothiol agglutinate human blood. The same occurs with iodine ionoide and of copper ionoide. The anti-pneumococcal, antidyenteric, antitetanic, antistreptococcal, antidiphtherial, and antimeningococcal serums also have all shown a marked power of agglutination. Nevertheless, in certain circumstances we do not hesitate to introduce into the veins these chemical substances and serums.

These different reasons show how exaggerated is the danger attributed to agglutination. Going further still in this demonstration, we have injected into both the right and left ventricle of a guinea-pig mixtures of horse's and human blood (Ragot), of horse's and dog's blood, which, though causing strong agglutination, did not result in any accident.

#### (b) Embolism.

We can well admit that the agglutination is an embolism in miniature; then embolisms are not necessarily a cause of accidents. We have been able to obtain a more significant demonstration by introducing into the circulatory torrent some cellular debris, and even solid but friable particles of stone mixed with a physiological serum. Our cellular debris was obtained by haemolysing horse's blood as completely as possible with distilled and sterilized water. By filtering this there is obtained a very coarse and granulated residue, composed of destroyed red cells of cellular debris; the residue is carefully and repeatedly washed in physiological serum and transfused into the dog after dilution with an equal volume of physiological serum.<sup>3</sup>

FIG. 1.

(a) The first period (A), the most important (the so-called "period of adaptation," or "dangerous"), is that in which the flow is slowest. At the end of the first minute hardly half a cubic centimetre of blood has passed; at the end of the second minute one or two cubic centimetres more have been transfused, to be followed by four more cubic centimetres of blood in the course of the third minute. The flowing then remains sensibly at the same slow rate for this first period, during which not quite a quarter of the total injected quantity flows in. The time is relatively long, as the length of it represents nearly a half of the whole length of time of the complete operation.

(b) The second period (B), so-called "constant rate," corresponds to the period during which the rate of flow is quicker than in the preceding period, and allows in a shorter time the passage of an amount of blood equal to or greater than that transfused in the first period. Towards the end of this second period the speed slackens so as to become equal to and sometimes less than the initial speed. This bend of the curve shows accurately the beginning of the third period (c).

(c) The third period (C), so-called "acceleration period," is that during which, in a shorter time still than in the second period, the rate of flow is quickened sharply and ends in full speed without any danger.

5. The heavier the animal, the greater is the increase in the rapidity of the flow, although there is no arithmetical progression, but the rapidity of the flow always presents the form of the curve described.

6. The rapidity of the flow also depends on the nature of the transfused liquid without the curve itself being modified. The greater the viscosity and density of the transfused liquids the slower the rapidity of the flow. If we take, for instance, a dog weighing 15 kilos the average of the flow can be 25 c.cm. a minute if physiological serum is used. If this serum is diluted one-half with horse's blood the rapidity of the flow will be from 12 to 15 c.cm. a minute; from 9 to 10 c.cm. if the horse's blood is pure or if milk is injected. It will be less than 9 c.cm. if a mixture of gum arabic is injected in quantities of 50 grams for one litre of physiological serum; lastly, the rate will be half a cubic

FIG. 2.

FIG. 3.—Human blood and blood of guinea-pig. No agglutination.

FIG. 4.—Horse's blood and human blood. No agglutination.

FIG. 5.—Dog's blood and horse's blood. Positive agglutination.

FIG. 6.—Human blood and colloidal iodine. Positive agglutination.

We were able to transfuse dogs with 100 to 200 c.cm. of this cellular debris in equal parts with physiological serum without perceiving the slightest accident. The introduction of cellular remains resulting from the haemolysis of red cells is not absolutely dangerous if the conditions of the rate of flow are fulfilled as we have indicated them.

Our experiments with particles of stone, which can be as large as from 15 to 20 $\mu$  across, are still more typical. So as to avoid accidents it is necessary to decrease the rate of flow in proportion to the number of particles in the injected serum. Thus a transfusion of 400 c.cm. of physiological serum containing 0.15 gram of stone has been made in a dog of 8 kilos at the average speed of 12 c.cm. a minute; but this rate was slackened to 3 c.cm. a minute for a transfusion of 130 c.cm. of serum containing 1 gram of stone.

The animal was killed five days later to determine what had become of the injected particles; they were found again everywhere in the blood, kidneys, lungs, and liver.

#### (c) Haemolysis.

We have shown that haemolysis is an independent phenomenon of agglutination. This haemolysis occurs nearly always in cases of transfusion of blood from animal to man. It is experimentally provoked in the transfusion of

blood from horse to rabbit or to dog; it occurs in mixtures whether *in vitro* or *in vivo*. This slight haemolysis does not result in any obvious accidents when the rate of the transfusion follows exactly the preceding established rules. The examination of the urines shows the presence of traces of albumin, with or without casts; the reaction of Meyer is positive. The presence of red cells is inconstant. There may be traces of urobilin. This urinary syndrome does not last a long time and its prognosis is good. It shows itself in the hours which follow the transfusion, reaching its maximum the next day and disappearing definitely after forty-eight hours.

#### Transfusion Accidents due to too Rapid Flow of Blood.

In contrast with what is believed, transfusion can be performed without any accidents, using homologous or heterologous blood, provided that the rules concerning the flow of the transfused blood are accurately followed. But if these simple rules are not followed and the injections are hurried we shall see these accidents happen, and the more rapid the transfusion the more severe they will be. When it is very rapid the animal quickly collapses and falls on its side in a few minutes. The beating of the heart becomes imperceptible, the rhythm of breathing is irregular,

accelerated, and even of the Cheyne Stokes type. Then come cries, shivers with tremors of the four limbs, trembling of the hind part, and contractures of the whole body; there are also nausea and vomiting. When the animal is unfastened it remains lying on its side, reacting no more to stimuli. Involuntary micturition and defaecation occur, and breathing ceases. The heart stops, the corneal reflex disappears, and the cornea looks glassy, the pupil of the eye dilates, and death ensues.

These accidents are sometimes only partial if the transfusion is slower. Nevertheless, when the conditions of the flow are not followed exactly as we have indicated them, the animal does not recover completely; it will be less bright, will not play, is somnolent and not hungry, at times passes blood in the urine and faeces; it is found dead twenty-four to forty-eight hours after the transfusion.

How are we to explain these accidents? Even when they are immediate, we do not think that this implies a real shock. We can, indeed, reproduce them at will, precipitate or slacken them according to the rate of flow towards the right side of the heart. Investigation shows that, in all these cases, the right side of the heart is dilated considerably, whether death be rapid or delayed for a few days.

Two forms are to be considered: the acute dilatation and the delayed dilatation.

(a) The very acute or primitive dilatation, which can be easily provoked with pure physiological serum if too quickly injected, is caused by a relatively considerable liquid mass pouring rapidly into the right cavities of the heart; it presses on the sides of the auricle and soon penetrates in the ventricle.

(b) The delayed or secondary dilatation appears when the accidents are postponed from two to eight hours, or even a little more. In that case considerable pulmonary lesions and infarcts are found. Sometimes a big clot of organized blood starts from the orifice of the pulmonary artery and reaches to its bifurcation. Then it may be believed that the dilatation of the right side of the heart is partly consequent on obstruction of the arteries of the lung. The too great speed of the transfusion has not allowed the too dense or too viscous liquid (blood, oil, milk, gum arabic) to pass in small portions through the capillaries of the lungs; consequently there is a hindrance more or less considerable, and a fatigue of the right part of the heart—an indication of a fatal sequel.

Thus we come back to a mechanism similar to that of the so-called pulmonary embolisms, those which happened formerly by the coagulation of the blood in the course of the transfusions in which sodium citrate was not used.

The pulmonary embolisms themselves are not necessarily harmful if they are made prudently and slowly. But as soon as the rate of the flowing is quickened, they might provoke, following the flow, an immediate or late death. So it was in our experiments with friable stone, particles of which, though larger than the red cells, had been perfectly tolerated by the organism so long as they were slowly transfused. Rapidly injected, they killed our dogs without exception.

The same remarks apply to the haemolysis which often happens during the transfusion. Haemolysis is insignificant and passes unperceived if the transfusion is made slowly. If it is done roughly it might provoke a certain disturbance of the kidneys, with pains in the loins and haematuria.

#### Conclusions.

The experimental and clinical researches which we have made during the past five years show that the transfusion of heterologous citrated blood is harmless in the following conditions:

1. It is necessary to make the transfusion very slowly; following the rules we have established.
2. The donor animal must be absolutely healthy and not have performed any great muscular work during the one or two hours previously.
3. The blood must be used immediately after its passing from the vein of the yielding animal.

4. As to the transfusion of blood from animal to man, we give the preference to horse's blood, which seems to be tolerated better than the blood of sheep or ox.

5. We do not advise the transfusion of pure horse's blood; it is better that it be diluted a third or half with physiological serum.

6. A good plan is to add adrenaline to the mixture to be transfused up to a strength of 1 in 1,000: five drops for 250 c.cm., or less.

7. Transfusion of horse's blood into man might be practised in the same way as intravenous injections of physiological serum.

#### IV.—E. I. SPRIGGS, M.D., F.R.C.P.,

Ruthin Castle.

DR. E. I. SPRIGGS spoke of the practical aspects of transfusion (1) after haemorrhage from the bowel; (2) as prophylactic against post-operative shock in malignant disease; and (3) in pernicious anaemia; and quoted illustrative cases, with charts showing the effect upon the percentage of haemoglobin and the number of red corpuscles. He continued:

As varying directions are given, I venture to mention in detail the actual method used. With rare exceptions no incision should be made, the blood being drawn from and put into a vein through a needle. After making sure that donor and patient are of the same group the two bloods are tested directly, against each other. The veins of the donor's arm are made prominent by putting the air-bag of the sphygmomanometer on to the upper arm and raising the pressure to 60 to 100 mm. of mercury, the fist being closed. A bandage or tourniquet is less efficient and is apt to obstruct the artery. The needle of a 10 to 20 c.cm. Record syringe is then thrust into the median basilic vein of the donor, attached by pressure tubing to a Potain aspirator, and, after letting down the pressure in the air-bag, the blood is drawn into a 4 per cent. citrate solution, of which 100 c.cm. are used to each 500 c.cm. of blood. The vein of the recipient is similarly punctured by a needle and a little blood allowed to flow back through the needle so as to fill it. The blood is then passed in from a flask-shaped bottle, which is kept warm with hot cloths, making sure that the tube from the flask and its connexion are full of citrated blood before fitting it on to the overflowing needle in the recipient's vein. The pump of a sphygmomanometer is used to force the blood in gently if it flows too slowly. To transfuse a pint of blood takes as a rule about three-quarters of an hour to an hour. Should the blood clot in the tube or needle—a rare occurrence—the needle is taken out and washed through with citrate solution. Sharp needles are essential, and spare ones should be available.

Fig. 1 shows the details of the apparatus used at Ruthin Castle.

1. After haemorrhage of the bowel the tedious recovery from the resulting

anaemia may be hastened by a transfusion. The following two cases may be compared in this respect.

CASE 1.—A man, aged 30; admitted May 14th, 1926. His height was 5 ft. 11½ in.; weight 12 st. 4½ lb. Gastro-enterostomy had been performed in 1922 for duodenal ulcer. He suffered in the following year from symptoms suggesting jejunal ulcer. In the spring of 1924 he had a severe haemorrhage. Melæna persisted

FIG. 1.—A, Needle to donor. B, C, Potain's aspirator. D, Bottle containing 4 per cent. sodium citrate, 100 c.cm. to 500 c.cm. blood. E, Pump of sphygmomanometer. F, Container. G, Needle to patient. H, Blood kept warm in jug of water.

for five to six days and has occurred at least twice since, the last time about October, 1925. On admission there was a secondary anaemia, the haemoglobin giving a Sahli index of  $43^{\circ}=51$  per cent.

CASE II.—A man, aged 48; admitted May 5th, 1926. His height was 6 ft.; weight 12 st. 2½ lb. In October, 1925, and March, 1926, he vomited blood. Investigation led to a diagnosis of duodenal ulcer. There was severe secondary anaemia; haemoglobin  $25^{\circ}$  Sahli=30 per cent.

These patients were comparable as regards their anaemia and its cause. They were both big men and both were treated in the same hospital at the same time, and with the same objects—namely, to aid the ulcer to heal, or, failing that, to get the blood into a suitable state for operation. Treatment consisted of rest, light diet, and iron. The first patient also had arsenic.

FIG. 2.—Cases I and II.

The only essential difference in the treatment in the two cases was that the older man (Case II) received a transfusion of 20 oz. of blood. The blood was of special value as it was taken from a patient with polycythaemia, fortunately a universal donor. The count of this blood at that time was 9,200,000 red cells with 128 per cent. haemoglobin.

The course of the recovery from anaemia in the two men is shown in Fig. 2, in which the percentages of haemoglobin during treatment are plotted out. The figures for the red corpuscles, which are not shown on the chart, showed similar increases.

The haemoglobin of the younger man, who was not transfused, rose in seven weeks from about 52 to 72 per cent.—that is, 30 degrees. That of the older man in the same time rose from 31 to 83 per cent.—that is, over 50 degrees. Of these it rose about 30 degrees in the three weeks following the transfusion.

2. The value of transfusion as a prophylactic against post-operative shock in those who are bad surgical risks is very great. Two cases may be cited.

CASE III.—A lady, aged 54, had had a gastro-enterostomy for gastric ulcer performed five years before admission. Ever since she had suffered pain and swelling to a degree which prevented her from taking enough food. She had been a complete invalid all the time and her weight had sunk to 6 st. 1 lb. Examination showed that the stoma let bile in but could not let food out. There was also evidence of distortion of bowel from adhesions.

FIG. 3.—Case IV.

For two months every effort was made, by complete rest, diet, medicine, etc., to improve the nutrition and lessen the discomforts of the patient, but without adequate result. At the end of that time her weight was 6 st. 2½ lb. She was unable to walk and was in no state for such an operation as is required in these cases, where adhesions have to be patiently dissected and anastomoses unmade or made, or both. A transfusion of 9 oz. was therefore given. The patient felt much better for it. An ischio-rectal abscess developed soon after. When this was well the patient later was able to bear a long operation, with much subsequent benefit.

In this case the transfusion was not given for anaemia, as the patient's blood standard was not far below that of a normal woman, but in order to increase her general strength and resistance.

CASE IV.—A woman, aged 65, was found to be the subject of a cancer of the pyloric part of the stomach. The symptoms were

of a year's duration. In that time laparotomy, suggested earlier, had been refused, a course of treatment with E.R.A. having been taken instead. It was desired to open the abdomen to see (1) whether gastrectomy was practicable or, if not, (2) to relieve obstructive vomiting. As a preparation two transfusions were given, one of a pint of the erythraemic blood used in Case II, and another, a week later, of 5 oz. of ordinary blood. A rigor occurred after the second transfusion. At operation the growth was found to extend from the oesophagus to the pylorus and was adherent to the liver. A short circuit was done.

Fig. 3 shows the effects on the blood. Note the rapid effect of the first large transfusion. So far from the operation depressing the state of the blood, it will be seen that the haemoglobin continued to rise after it.

The way in which this weak and elderly lady bore the operation was remarkable. It was said at the time that she showed no more shock than a healthy young soldier after a simple laparotomy. The patient's symptoms were relieved. She died five months later, with jaundice, without suffering, and did not know the true nature of her illness.

3. In pernicious anaemia transfusion offers the most valuable means we have of improving the state of the blood in cases in which there is still a downward tendency after treatment by removal of septic foci, rest, good food, hydrochloric acid, and arsenic. It is suggested that small quantities of blood may be as useful as large. A conclusion on such a point must be formed on the results from a great number of cases. The greatest improvements we have seen have been from large transfusions of erythraemic blood; and the benefit to the patients' blood did not fall away in a few days. This suggests that it is advantageous to put in as much haemoglobin and as many red corpuscles as practicable—subject, of course, to adequate preliminary tests being made.

Here is a case in which no immediate benefit was received from two small transfusions from the patient's own sons.

CASE V.—A woman, aged 65. Two years' history. The first transfusion was followed by a mild rigor and herpes labialis. The appetite improved and fatigue was less, but the blood remained as before. Some weeks later improvement in the general state was reported.

In the following case great benefit was received from three successive transfusions.

CASE VI.—A man, aged 54, had been regarded as neurasthenic for some years. He had felt weak for a year and had lost weight, but four months earlier his blood counts had been normal. The nature of his illness, which was acute, was not evident until admission. He had septic teeth, glossitis, and achylia. Arsenic was administered under the skin, with total rest and suitable diet, but the patient's downward course continued, the haemoglobin falling to 20 per cent., and the red corpuscles to 1,000,000. His clinical state was serious. A pint of blood from a patient with polycythaemia was then given. The veins, like the tissues generally, were small and shrunken, and it was not found possible to puncture one through the skin. An incision was therefore made and a cannula tied in. After the transfusion the patient began to improve at once. A fortnight later 10 oz. of blood from an ordinary donor was given. At this, as well as at a later transfusion, a vein could be pierced, owing to the better state of the circulation; and the usual closed method was used.

FIG. 4.—Case V.

FIG. 5.—Case VI.

Fig. 5 shows the initial downward course of the blood in this patient and the great improvement after the first transfusion. When the patient became strong enough the offending teeth were removed, and as soon as the haemoglobin reached 40 per cent. he began to get up. He left taking regular walks. The haemoglobin was 60 per cent., red cells 2,500,000.

The procuring of donors is a real difficulty, especially as a proportion of those who offer are not entirely healthy or do not belong to the right groups. In a hospital there are often some patients who need venesection for severe hyperpæmia, or, more rarely, polycythaemia, and in a few of these the blood may be suitable to use for others. A general organization of healthy donors in each district is needed.

#### V.—GEOFFREY KEYNES, F.R.C.S.,

First Assistant, Surgical Professorial Unit, St. Bartholomew's Hospital.

#### BLOOD TRANSFUSION IN SURGERY.

THE contribution which I have been asked to make to this discussion is to deal with the surgical aspect of the question. It is difficult to set any precise limits to the surgical applications of transfusion, but I can at any rate avoid reference to the primary anaemias and to other diseases belonging as obviously as these to the province of the physician.

The recognition in this country of the value of transfusion in surgery has been of comparatively slow growth; it is, however, now very well established, and promises to become an operation performed almost daily in any large hospital. There was formerly some difficulty in obtaining an adequate supply of blood donors, and in a communication on this subject made to the Surgical Section of the Association in 1924, I suggested that these might best be supplied through the Red Cross organizations. A supply of voluntary donors to some of the London hospitals had, as a matter of fact, already been started by the individual enterprise of Mr. P. L. Oliver in 1922, and his organization has recently been recognized and taken over by the British Red Cross Society. This branch of the society's activities is known as the Blood Transfusion Service, and is now playing a large part in the development of blood transfusion as an adjunct to surgery in London. I have been permitted to use the reports received by this service during the last four years (June, 1922, to May, 1926) from all the London hospitals, and I think that information based on the comparatively large number of transfusions thus made available for analysis will carry more conviction than if based only on my own experience. Any favourable or unfavourable conclusion that may be reached will at any rate be free from the charge of personal bias.

The supply of blood donors has kept pace with the increase in the demands of the hospitals, which advanced from 13 in 1922 to 428 in 1925. The total number of calls for donors so far received by the Blood Transfusion Service is in the neighbourhood of 700, and nearly a third of these were received in the first five months of 1926. It is of interest to notice the proportions in which the transfusions actually performed were distributed between the various types of case:

|                    |     |     |     |     |     |
|--------------------|-----|-----|-----|-----|-----|
| No report received | ... | ... | ... | ... | 144 |
| Medical diseases   | ... | ... | ... | ... | 158 |
| Surgical diseases  | ... | ... | ... | ... | 250 |
| Gynaecological     | ... | ... | ... | ... | 69  |
|                    |     |     |     |     | 319 |

The gynaecological patients were divided between acute secondary anaemia, sepsis, and surgical operations, and may therefore be reckoned in the surgical score. If those cases in which no report was received be divided between medical and surgical in the same proportion as those which were reported, we arrive at the final figures of—

|          |     |     |     |     |     |
|----------|-----|-----|-----|-----|-----|
| Medical  | ... | ... | ... | ... | 206 |
| Surgical | ... | ... | ... | ... | 411 |

or almost exactly two surgical for every one medical case treated by transfusion. This is some indication of the present relative value of transfusion in surgery.

I will now give a further analysis of the surgical cases in order to discover for what types of patient transfusion is chiefly used, and what the results have been. It at once

becomes clear that by far the largest group—no fewer than 121 out of a total of 221 in general surgery—falls into the category of "gastric or duodenal." The types and results are as follows:

*Gastric and Duodenal Type* (121 cases).—Ulcer, acute or chronic; or carcinoma of stomach, with or without haematemesis or melæna, or both, or preceding or following operation.

|                                       |     |     |     |     |    |
|---------------------------------------|-----|-----|-----|-----|----|
| No benefit                            | ... | ... | ... | ... | 18 |
| Temporary improvement, but died later | ... | ... | ... | ... | 13 |
| Result good or very good              | ... | ... | ... | ... | 90 |

*General Surgical Type* (100 cases).—Including amputation of leg, splenectomy, carcinoma of colon, carcinoma of bladder, thoracic tumours, nephrectomy, street accidents, secondary anaemia from various causes, etc.

|                          |     |     |     |     |    |
|--------------------------|-----|-----|-----|-----|----|
| No benefit               | ... | ... | ... | ... | 4  |
| Temporary improvement    | ... | ... | ... | ... | 6  |
| Result good or very good | ... | ... | ... | ... | 90 |

*Haemophilic* (4 cases).

|             |     |     |     |     |   |
|-------------|-----|-----|-----|-----|---|
| No benefit  | ... | ... | ... | ... | 1 |
| Result good | ... | ... | ... | ... | 3 |

*Septicæmia and Pyæmia* (25 cases).

|             |     |     |     |     |    |
|-------------|-----|-----|-----|-----|----|
| No benefit  | ... | ... | ... | ... | 22 |
| Result good | ... | ... | ... | ... | 3  |

*Gynaecological Type* (69 cases).

|                          |     |     |     |     |    |
|--------------------------|-----|-----|-----|-----|----|
| No benefit               | ... | ... | ... | ... | 7  |
| Temporary improvement    | ... | ... | ... | ... | 4  |
| Result good or very good | ... | ... | ... | ... | 58 |

It is at once evident that the results in general are excellent, except in the group "Septicæmia and pyæmia," where very little benefit has followed transfusion. My personal experience on a smaller scale fully agrees with the results set out above. It is, of course, impossible to say of any given patient that he would have died had he not been transfused, but it is equally impossible to avoid the conclusion that transfusion has given a substantially increased margin of safety where so large a measure of satisfaction has been so widely expressed.

The value of transfusion in such surgical conditions as hæmophilic hæmorrhage, traumatic hæmorrhage, and, indeed, most forms of acute secondary anaemia, is now fully recognized, and I need not emphasize this point. There is, however, one group of patients—namely, the "gastric and duodenal" group already referred to—in which the value of transfusion has been somewhat slow to receive its proper recognition, although my own experience seemed to show that it was very great. It was with special interest, therefore, that I discovered from the reports of the London Blood Transfusion Service how large a number of these patients are now receiving transfusion. I feel, as a surgeon, that it is here that blood transfusion is enabling a stride forward to be made, for lives are being saved which otherwise would have been lost. Transfusion in these cases may serve a dual purpose: it may prevent the death of the patient from actual loss of blood, and it may make possible a necessary operation which, without transfusion, would be impossible. It is therefore applicable to cases of bleeding from acute ulcers, in which operation is seldom necessary; to cases of bleeding from chronic ulcers, innocent or malignant, in which operation is often necessary; and to operations in general upon the stomach and duodenum, which tend to be very severe, and therefore to be attended by much "operative shock." Transfusion may, of course, be used with great advantage to give the patient an increased margin of safety in all operations of particular severity, but I shall confine my remarks to the gastro-duodenal group, and illustrations taken from this group will cover all the points I wish to make.

Transfusion used to be withheld in cases of gastric or duodenal hæmorrhage for two main reasons: (1) It was stated by some authorities that patients never die from hæmorrhage from a gastric or duodenal ulcer, and it was therefore said to be unnecessary either to transfuse or to operate. (2) It was believed that there was an actual danger in transfusion, and that the ensuing rise of blood pressure would result in further hæmorrhage.

The first statement I believe to be untrue, the second to be based upon a fallacy. Working in a big general hospital I have seen a large enough number of *post-mortem* examinations of patients who had died from sheer hæmorrhage from a gastric or duodenal ulcer, to be convinced that

patients die fairly often from this cause. Furthermore, the necropsies showed that, without either transfusion or surgical intervention, death from haemorrhage was inevitable. I may illustrate this point by a drawing made from a specimen recently removed at necropsy (Fig. 1). In the centre of the floor of a large chronic ulcer is an eroded blood vessel which has bled and become occluded. At the edge is a second larger vessel standing up in the ulcer with a big recent erosion in its wall. It would have been almost

FIG. 1.—Drawing of a chronic gastric ulcer, showing healing of one erosion in a blood vessel (represented by the two black dots), with subsequent erosion in another place. The patient was transfused after the first haemorrhage and survived; he died from the second haemorrhage.

life without an adequate volume of fluid in the circulation. The strain falls mainly, therefore, upon the heart, and the first effect of the transfusion is to relieve the heart of this excessive burden. The rise of blood pressure which follows transfusion is consequently neither so great nor so sudden as to be likely to dislodge a clot plugging the eroded vessel. There is also the very important effect of the transfused blood in promoting the coagulation process and, thereby, reinforcing the clot already formed. This is due partly to the properties of the new blood that is introduced, and partly, if citrated blood is used, to the paradoxical action of sodium citrate in actually increasing the coagulability of the blood when introduced into the circulation. The accompanying drawing (Fig. 2) will illustrate what happens if this clot formation is successful. The specimen was taken from a patient who had died

FIG. 2.—Drawing of a longitudinal section (x8) through an eroded blood vessel in the floor of a chronic gastric ulcer, showing the extent of the thrombus which has formed in the mouth of the vessel.

from another cause. The vessel is in the floor of a chronic ulcer, and is quite unable to retract. The clot extends for a considerable distance along the lumen and is organizing, so that digestion or further loosening is very unlikely.

Conditions in the individual patients are so various that more detailed statistical analyses of the reports of the London Blood Transfusion Service or from our own hospital records will not be of much value. The rapid extension of the use of transfusion in these cases is the best proof of its efficacy. It cannot, I think, be denied that there

is a certain proportion of patients who must inevitably die without the aid of surgery. It is, moreover, certain that operations on them cannot be undertaken without the aid of transfusion. The actual results of surgery have not in the past always been good because our medical colleagues have tended to offer us for operation those patients whose condition was already desperate. Even among those, as the reports of the Blood Transfusion Service in several instances ("patient moribund") show, lives have been saved by transfusion, and in the cases that have come under my own observation the results are improving with experience. I may illustrate this by an account of three patients recently treated in the wards of the Surgical Unit at St. Bartholomew's Hospital.

#### CASE I.

A dock labourer, aged 57, had had symptoms of gastric ulcer for six years, but had never vomited blood until May, 1921, when he was actually in a medical ward at St. Bartholomew's Hospital with Professor Fraser undergoing treatment with Lenhart's diet. He afterwards improved, but had a recurrence of haematemesis in August, 1923. He was readmitted to a medical ward at St. Bartholomew's Hospital and had a severe haematemesis on three consecutive days. He was then extremely anaemic, and appeared to be almost moribund when he was transferred to the Surgical Unit. A blood transfusion of 900 c.cm. was given at 5 p.m. on August 26th, and four hours later an operation was done by Mr. T. P. Dunhill. The stomach was opened and a bleeding point in the floor of an ulcer near the pylorus was cauterized. A posterior gastro-enterostomy was performed. The patient made an uninterrupted recovery, and there can be no doubt that his life was saved by the transfusion and operation.

FIG. 3.—Case II. Blood pressure and pulse rate curves taken during operation and transfusion for acute gastric haemorrhage.

#### CASE II.

A woman, aged 29, had had symptoms of gastric ulcer for over two years. In 1921 she had haematemesis while in hospital, and this recurred in 1923, while she was being given Lenhart's diet. She was then transfused with 500 c.cm. of blood, but this did not arrest the bleeding, and haematemesis recurred on several successive days. She was transferred by Professor Fraser to the Surgical Unit on July 9th, 1923, when she was blanched, sweating, and restless. Her red blood cells had fallen to 2,000,000 per c.mm. and the haemoglobin to 35 per cent. An exploratory laparotomy was done on the same day by Professor Gask. The stomach was examined, but no lesion could be discovered from the outside. It was therefore opened through its anterior surface. A small ulcer with an eroded vessel in its base was then seen on the posterior wall. The mucous membrane was sewn over the ulcer, and the stomach and abdomen were closed as quickly as possible. A blood transfusion was begun about fifteen minutes after the operation had started and was continued through the critical stages, 850 c.cm. being given. The patient was in a very low state, the blood pressure being below 100 mm. at the beginning of the operation, and having fallen to 80 mm. when the transfusion was begun; it gradually rose from this point, and was 120 mm. at the conclusion of the operation (Fig. 3). The patient made an uninterrupted recovery. Two days after the operation the red blood cells had risen to nearly 4,000,000 per c.mm. and the haemoglobin to 65 per cent., and the improvement continued afterwards.

#### CASE III.

A man, aged 39, had had symptoms of pyloric ulcer for ten years. On May 23rd, 1923, he had severe haematemesis and melaena. He was transfused with 600 c.cm. immediately after admission to St. Bartholomew's Hospital under Dr. Morley Fletcher, his condition being extremely serious. On the following day he had improved; his red cells numbered 2,400,000 per c.mm. and his haemoglobin was 50 per cent. He was not, however, seen by a surgeon as the physicians regarded him as being too ill for any operation. He remained in the medical ward for the next month. He had no further haematemesis, but the bleeding continued in a lesser degree, as shown by occult blood in the stools and by an occasional melaenic stool. On June 28th his condition was still very bad. His red blood cells and haemoglobin remained at almost exactly the same level as on the day after admission. He was then transferred to the wards of the Surgical Unit. On July 2nd Professor Gask performed a laparotomy and found an indurated mass at the pylorus with general oedema of the stomach wall. A posterior gastro-jejunostomy was done. During the operation the patient was given a massive transfusion from two

donors. First 700 c.cm. were injected rapidly during the initial stages of the operation. This was followed by a second 700 c.cm., given more slowly during the critical stages of the operation. The result is shown by the systolic blood pressure curve, which began at 120 mm. and finished at 140 mm. (Fig. 4); it never fell below 110 mm., this point being reached between the end of the first transfusion and the beginning of the second. The patient made a good recovery. On the evening of the same day his red blood cells had risen to over 4,000,000 per c.mm., and three days later his haemoglobin was still at 63 per cent. (Fig. 5).

FIG. 4.—Case III. Blood pressure curve taken during operation with massive blood transfusion for chronic gastric haemorrhage.

operation for partial gastrectomy was undertaken by Professor Gask on June 8th, 1926. The patient was a thin, debilitated girl, and arrangements were made to transfuse her during the operation. The stomach was found to be involved in extensive adhesions and a partial gastrectomy was done, the operation reaching the extreme limit of what was technically possible and lasting for over two hours. The transfusion was begun towards the end of the first hour and 800 c.cm. of

FIG. 5.—Case III. Red blood cell and haemoglobin curves showing the effect of operation with transfusion.

blood were given during the next eighty minutes at the rate of 100 c.cm. every ten minutes. The blood pressure fell gradually during the operation, but the systolic pressure never fell as low as 100 mm. and had risen to 120 mm. at the end (Fig. 6). The transfusion was believed to have played a considerable part in maintaining the patient's good condition during so long and severe an operation.

I cannot now add much under the heading of technique, but it is important to establish, if possible, the optimum time for the transfusion. Experience shows that if transfusion is given purely with a view to replacing blood lost

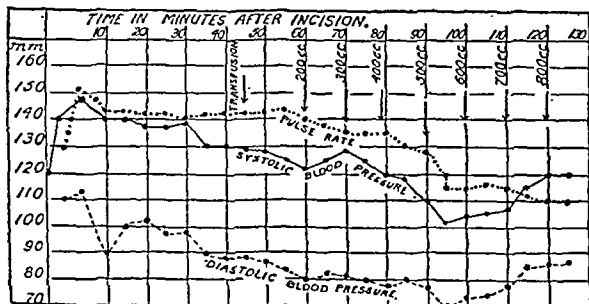

FIG. 6.—Case IV. Blood pressure and pulse rate (dotted line) curves taken during operation with blood transfusion for a difficult gastrectomy, the transfusion being spread over eighty minutes as indicated by the arrows.

and discouraging further haemorrhage, as in acute ulcer, it should be done without delay. If the patient be seriously ill with haemorrhage from a chronic ulcer which is to be dealt with by operation, I believe the ideal procedure is to give two transfusions, one a few hours before operation and the second while the operation is actually proceeding. As Professor Gask has remarked to me, an operation conducted in this way, with the blood being injected into one arm and the blood pressure being recorded in the

other, is like a physiological experiment. The team is disposed as in the accompanying diagram (Fig. 7), and the

FIG. 7.—Diagram showing the disposition of the team during an abdominal operation accompanied by blood transfusion. The blood pressure and pulse rate are systematically recorded during the operation.

transfusion is timed to coincide with the stage at which the patient is likely to feel the maximum effects of the shock. If the transfusion is successfully carried out the shock never occurs at all.

Transfusion has, admittedly, not always succeeded in the past in saving patients' lives. The reason for some of these failures has been that either the transfusion was withheld for too long, or, having been given, was not pushed with enough vigour. Two or more transfusions may be necessary in the really serious cases, and hesitation will only stultify the treatment.

#### GENERAL DISCUSSION.

Dr. F. B. SMITH (Harrogate) wished to draw attention to the still present possibility of alarming reactions following transfusions, in spite of negative agglutination reactions between the cells and serum of both donor and recipient, tested reciprocally. Among forty transfusions this had occurred in one patient, who had altogether four transfusions for a prolonged and severe relapse in pernicious anaemia. Three of the transfusions had been within a period of ten days, the fourth about six weeks later. The two alarming reactions occurred after the third and fourth transfusions, each commencing about half an hour after the completion of the transfusion, and simulating a severe rigor and collapse, with disappearance of the radial pulse.

Professor GRAHAM (U.S.A.) expressed his gratification at the results of blood transfusion in well selected cases. He drew particular attention to its value in cases of severe burns where exsanguination followed by transfusion might be of great service in combating the toxæmia.

Dr. ROBERT PLATT (Sheffield) put in another plea for the use of defibrinated blood. Some of his cases had already been published (*Lancet*, January 23rd, 1926, p. 173), showing that far fewer reactions followed the use of this method. Sir Humphry Rolleston had said that in from 9 to 66 per cent. of cases reactions followed the introduction of citrated blood, but in 66 transfusions of defibrinated blood only 4 patients had rigors, and 3 of these were febrile cases of pernicious anaemia, which were the most prone of all cases to develop reactions. Colebrook and Storer recorded a similar freedom from reactions using defibrinated blood. He disagreed with the statement that citration was the easiest method, since nowadays defibrination was just as simple and did not necessitate an available supply of sterile citrate solution. In 13 cases of septicaemia and pyaemia transfused by this method there was a marked fall of temperature and great clinical improvement in 7, while in 4 others there was temporary improvement.

# OBSERVATIONS ON TWENTY-FIVE CASES OF PROSTATECTOMY.

BY

RALPH COYTE, M.B., B.S.LOND., F.R.C.S.,

ASSISTANT SURGEON TO ALL SAINTS' HOSPITAL AND THE QUEEN'S HOSPITAL FOR CHILDREN; SURGICAL REGISTRAR, PRINCE OF WALES'S HOSPITAL, TOTTENHAM.

DURING 1925 I had under my care in All Saints' Hospital 25 cases of enlarged prostate for which prostatectomy was performed. These cases I have subsequently followed up in the out-patient department for the ensuing two months or longer.

The average age of the patients was 60—the youngest being 49 and the eldest 73. The mortality was one; this patient died on the sixteenth day after operation from a pulmonary embolus. He exhibited the usual symptoms; he was taken with a sudden desire to defaecate, and while on the bed-pan fell back dead.

Of the 25 operations, 20 were by the one-stage and 5 by the two-stage method. In the selection of method I have been guided by three factors:

(a) *The Clinical Picture.*—Patients rred for tongue, persistent headaches, loss of meat), and the passage of scanty ur for a two-stage operation.

(b) *Cystoscopy.*—This I have done as a routine, and is, in my opinion, of the greatest value, in that it demonstrates the degree of sepsis within the bladder. A gross degree is only suitable for a two-stage operation. While the cystoscope is in position the kidney function can also be tested by intravenous injection of indigo-carmin.

(c) *Urea Concentration Test.*—Where the final concentration falls below the 1.5 mark I think the two-stage operation should be adopted.

As regards the actual operation, the first 8 cases of this series were treated by putting a large drainage tube (bore 1 in.) in the bladder, without packing the prostatic cavity. In two of these cases fairly severe haemorrhage occurred two hours after operation. In the remaining 17 cases I have packed the prostatic cavity for forty-eight hours. I find there is often a little bleeding on removing the packing, but it is never serious; and although the procedure causes a certain amount of pain this can easily be controlled by morphine. I always pack the cavity with two fingers in the bladder, and without widely retracting the edges of the bladder wall, as I consider that the latter procedure somewhat increases the shock of the operation.

The tube is removed on the sixth day, and the patient then washed per urethram with a solution of 1 in 10,000 silver nitrate once a day. The average time taken for the suprapubic wound to heal has been twenty-four days—the quickest being sixteen, and the longest thirty-five days. The patients taking the longest time to heal have all been markedly obese.

Complications met with have been epididymitis in 7 cases: these all subsequently cleared up. There was one case in which the suprapubic wound reopened five weeks after discharge from hospital; this man had at the time of operation a stricture in the penile urethra which had previously been dilated; after operation he did not come up for treatment as advised, but on dilatation of his stricture the fistula rapidly closed. In one case the symptoms were not relieved by the operation, and by posterior urethroscopy I discovered that this man had developed an obstruction in the shape of a prostatic ledge. This I dealt with by diathermy through the urethroscope, and the patient is now in good health. The remaining patients made uneventful recoveries, and have since been quite well. Sections of the prostates were made after removal. In one case an early adenocarcinoma was found to have commenced: this man is still quite well nine months after operation. Some of the glands after removal showed small areas of normal prostatic tissue around the adenomatous portion, and the fatal case showed normal prostatic tissue remaining around the cavity. These latter findings show that it is impossible to remove the prostate completely, and that the operator must leave sufficient normal tissue for a further potential adenomatous enlargement.

# THE INHIBITION OF INSULIN ACTION BY TOXAEMIAS AND ITS EXPLANATION.

A Preliminary Communication.

BY

R. D. LAWRENCE, M.D.\*

CHEMICAL PATHOLOGIST, KING'S COLLEGE HOSPITAL.

THE effect of toxæmias and different forms of sepsis in reducing insulin action in diabetes is one of its chief puzzles and the greatest weakness of insulin therapy. All workers are agreed that sepsis and infections make diabetes worse, are a common immediate cause of coma, and that their onset requires a greatly increased dosage of insulin to produce the same effect. The problem of this inhibition of insulin action is therefore of great physiological and therapeutic importance. It was thought that the cause that prevented the usual action of insulin in septic conditions would most likely be the production of a metabolic condition that failed to respond to insulin in the usual way, and the failure would not be due to direct chemical inhibition of insulin by the circulating toxins.

The easiest way to attack the problem seemed to be to try to produce an insulin-resistant condition in normal animals by toxins and to observe any accompanying changes which might account for the failure of insulin action. Various toxins have been tried on rabbits, and the clearest results have so far been obtained by diphtheria toxin. With this a condition has been produced in which the power of insulin to reduce blood sugar has been greatly diminished and sometimes abolished altogether. At the same time extensive pathological changes have been observed in the thyroid and adrenal glands which would appear to be the cause underlying the inhibition of insulin action. The details of these experiments and a number of curious observed facts in connexion with insulin action will be published soon in the *British Journal of Experimental Pathology*, but it is considered desirable now to give a summary of the work, as it is of clinical as well as experimental interest.

## Rabbit Experiments.

It has been found that when normal rabbits are given a dose of diphtheria toxin which kills them in about four to eight days, a dose of insulin which previously caused a considerable drop of blood sugar fails to do so. This usually does not take place on the first day, when the animal is at the height of its pyrexial reaction, but becomes most noticeable when the action of the toxin is fully established. On certain days, indeed, insulin has been observed to raise, and not to lower, the blood sugar concentration. These points have been repeatedly observed after the injection of diphtheria toxin.

Histologically, striking changes have been observed in the thyroid and adrenal glands of these animals, and to a greater degree than in the other organs examined. The thyroids showed great congestion, disappearance of the colloid, and destruction and confluence of many of the alveoli. In the adrenals congestion and signs of complete exhaustion and disappearance of the lipid were observed. Such changes in the adrenal are a well known result of death from diphtheria toxin, and are, indeed, used to distinguish true diphtheria from diphtheroid organisms.

## The Significance of these Experiments.

The thyroid and adrenal glands and their extracts are known to be direct physiological antagonists to insulin. This has been shown quite clearly in animals and in man by the simultaneous injection of adrenaline, which is found to prevent the usual action of insulin in lowering blood sugar. It has also been shown that thyroid feeding in animals greatly reduces the usual action of insulin. And, from the clinical point of view, the disturbance of carbohydrate metabolism and resulting glycosuria in hyperthyroidism and the hyperadrenalism of excitement is well known. It would appear clear, therefore, that an agent which stimulates the thyroid or adrenal, singly or together, would antagonize the usual action of insulin.

\* Working on insulin for the Medical Research Council.

qualified and reputable practitioner in the area. In a general hospital of a city such arrangements would be impracticable; it would mean disorder and injury to patients. The wise man knows his own limitations; he does not want to dabble with costly radiographic apparatus or attempt operations the like of which he has never seen. Nevertheless, there is still room for the expansion of our big hospital staffs. I read that in New York City a census taken on the 1921 directory showed that of 8,760 physicians practising in the city no fewer than 3,232, exclusive of consultants, had affiliations with hospitals in the capacity of visiting or assistant visiting physicians or surgeons. This constituted 36.8 per cent. of all registered medical practitioners in the city. Again,

"There exists no absolutely 'closed' staff, as every hospital (outside of purely research institutions) has a so-called 'courtesy' staff consisting of men who are given the privilege of sending in private patients and attending them at the hospital. . . . These privileges refer almost invariably to private or semi-private accommodation and very seldom to public wards."

The association of more doctors with hospital work is shown by this citation to be bound up with the enlargement of the hospital idea, that it should no longer be for the sick poor only but for all. The limited "house of pity" conception ought to be dead, but it dies hard. It is damaging to the hospitals, to the profession, and to the public. Osler wrote in 1908:

"It has always seemed to me a radical defect of the English hospital system that, as a rule, no provision is made for pay patients. Not only should the class . . . with moderate means be allowed to use the general hospitals on special occasions and pay what they could for services, but it would be an immense boon to extend the privileges of the hospital to the well-to-do classes by the establishment of pay wards."

Now, nearly twenty years later, there is a move, in a small way, to meet this radical defect. It should be our endeavour as a profession to foster it in every way. In the next few years the growth of such accommodation will, I believe, be rapid. Legislation is foreshadowed for the registration of nursing homes, with a view to the improvement of these places for the sick. Improvements cost money. It is likely, therefore, that some of these homes will go out of business from inability to meet new capital outlay. The existing accommodation, especially that which the middle classes can afford, will become more limited; and just at a time when domestic difficulties render the care of the sick at home less possible. The demand for hospital accommodation, pay wards, or special hospitals will certainly increase.

The out-patient department is still a blot upon our hospitals, albeit less now than formerly. It is a relic of the bad old times when pauperism was normal for the major part of the population. The caustic comment upon this indiscriminate medication to be found in the minority report of the Poor Law Commission is not too severe. It may be said that it should be banned in its present form, since it is in conflict with the principle of Florence Nightingale: "the very first requirement in a hospital that it should do the sick no harm." There is now no need for it except for consultation purposes, since insurance and provident practice is so thoroughly established and efficient in its working.

#### Questions.

There are certain questions that will inevitably arise when we consider this modern hospital conception.

*Will such a scheme increase hospital abuse?* I think it will end it. When the hospital receives all classes of patients—poor, part-paying, and wholly-paying—what is called hospital abuse will disappear. An efficient almoner system (such as we are developing) will place each patient in his proper category. Individual hospital abuse is, in my experience, declining. The grossest abuse now arises from the exploitation of hospitals by wealthy corporations; with this I will deal later.

*Will the larger hospital conception endanger provision for the poor?* By no means. I think it will enhance it. It most certainly will give the poor confidence in an institu-

tion to which all classes resort—themselves, the workers of all kind, and even the rich.

*Will such a scheme mean State control?* I think it will prevent it. Closer organization in the working of our voluntary hospitals would so secure them in their prominent position that State hospitals would be likely to be drawn into their wake for their own good.

*Will it mean a loss of local interest and therefore of benefactions, especially if the State helped such a scheme financially?* I do not think so. The better the scheme and its working the better the appeal it makes. It seems to be assumed by some that State grants mean the automatic loss of gifts and subscriptions. I should like to see the evidence of this. We do not find it true of the universities. Even county council schools have received benefactions! It is not true of the societies for the blind, for though in the last five years State grants have increased tenfold, private benefactions have steadily increased. It is not true of New Zealand, where a State hospital system, under semi-independent control, has received large benefactions.

*Will such a scheme mean the general remuneration of the staffs?* Yes, undoubtedly. You cannot have paying patients in a hospital, whether they pay in part or in whole, without depriving the staff of some of their means of livelihood. The medical members of hospital staffs must live, even as others, on their work. The proposition is no new thing. There is found among the records of St. Bartholomew's Hospital, in the time of Harvey, this minute:

"That Dr. Andrewes be now advanced to be also an immediate physician to this hospital, and to have the salary or yearly fee of £33 6s. 8d. for his pains."

There is a good custom in vogue in at least one New York hospital.

"The highest salaries are paid to the younger members of the visiting staff. The basis for this is that the younger members give more time to the institution; when they become older and their income from private practice increases, their salary is decreased. The other consideration is that it relieves the younger men to a certain extent from their bread-and-butter worries and makes it easier for them to apply their time to research and study."

#### Hospital Abuse.

Earlier I said the grossest form of hospital abuse was that due to the exploitation of hospitals by wealthy corporations. I will now justify this statement. There is an ever-increasing number of cases admitted to hospital as out- and in-patients because of industrial accident or disease. These patients are under the protection of the law as regards compensation for loss of wages during illness or loss of earning power thereafter. But there is no provision for their treatment other than by their insurance doctors. The gap has to be filled by the hospitals at the expense of the charitable and of the hospital staffs. Another group of cases come into hospital suffering from street accidents. In both groups of patients a third party is interested in, and benefits by, their speedy recovery—the wealthy insurance companies. But it does not seem to have occurred to them, or with rare exceptions, that they have a duty to the doctors who step into the breach and tend these patients. There is ample precedent for such an arrangement, and failing one arrived at by friendly adjustment we should seek an amendment of the law. In New York State it is provided by law that the party responsible for compensation shall also pay the hospitals and the medical staffs for the treatment of these cases. There can be no doubt that at the present time shareholders of insurance companies are profiting at the expense of the hospitals, and the private benefactions which we may hope these shareholders make do not indemnify them against the charge of exploiting charities and the medical staffs of those charities for business purposes.

Mr. Chairman, that concludes my address. My aim has been to present a conception of something better than we have to-day, wonderful as that is when it is compared with a past that is possibly within the memory of some here.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### PYLORIC STENOSIS.

The following case seems noteworthy on account of its comparative rarity and rapid recovery under diet and without operation.

A female infant showed all the clinical features of congenital pyloric stenosis. The child had been under other treatment, but the history of the earlier weeks is given by the father, who has proved himself a careful observer. The child, which was born on December 9th, 1925, and was breast-fed, began to vomit during the third week; at first this occurred occasionally, but later after every feed. The bowels became constipated and the child began to show signs of wasting. The treatment had consisted in starvation for a period of twenty-four hours, glycerin suppositories, and various medicines by the mouth. The weighings, though not accurate, are not without significance: Birth, 7½ lb.; 22 days, 9½ lb. (with clothes); 26 days, 8½ lb. (with clothes).

I saw the infant first during the eighth week and advised that it should be put to the breast for fifteen minutes every three hours (daytime) and four and a half hours (night-time). Grey powder thrice a day and sodium citrate between meals were given. During the first two days the child vomited every feed. Vomiting was expulsive in character and contained much mucus. On examining the abdomen visible peristalsis was very marked after feeding and the pylorus was easily palpable.

The diet was altered to ten-minute feeds every two hours (day-time) and every three hours (night-time). Sodium citrate was continued, while the grey powder was substituted by maglactis as being more easily given. The result was that vomiting became less frequent though more copious, indicating more than one feed. It frequently took place as soon as the child was put to the breast. The bowels were becoming less constipated.

On February 8th the weight was 8 lb. The bowels kept moving on an average thrice daily. During the following week vomiting was reduced by about one-half and the child had put on three-quarters of a pound in weight.

To satisfy the parents that the feeding was not at fault it was agreed to give alternate feeding, using as alternative cow's milk dilution. Sodium citrate and maglactis were continued as before, but were given immediately before the feed. The result (a week later) proved that the patient showed no partiality towards artificial feeding, as vomiting was as frequent after the bottle feed as after the breast feed. During this week the child lost a quarter of a pound in weight.

On February 28th breast-feeding alone was adopted, being given for six minutes every two hours with two night feeds; during this week the child vomited on four occasions only and the weight increased by three-quarters of a pound. Thereafter vomiting gradually ceased, and the weekly weighing records were as follows:

March 7th, 10½ lb.; March 14th, 11½ lb. The diet was now changed to nine-minute feeds every three hours (seven feeds in twenty-four hours), with the following result. On March 21st the weight was 13½ lb.; on March 28th, 12½ lb.; on April 4th, 12½ lb.; and on April 11th, 13½ lb.

The giving of the slightly laxative antacid before feeds seemed to have most effect in allaying the discomfort in the stomach as well as counteracting the resulting constipation.

Saltcoats, Ayrshire.

A. SMITH GOUDIE.

#### PULMONARY EMBOLISM FOLLOWING CHILDBIRTH.

IN the BRITISH MEDICAL JOURNAL of November 6th (p. 835) two cases of pulmonary embolism following childbirth were recorded. A case very similar to that reported by Dr. Young came under my care two years ago.

A strong, healthy primipara was delivered of a full-time healthy girl, quite normally, and exactly ten days after she had a small pulmonary embolism. Fortunately it did not prove fatal, but her life was in danger for several days. Unfortunately she developed a very bad bedsores through being kept perfectly still for a time in a half-reclining position.

Wolverhampton.

F. D. SPENCER, M.R.C.S., L.R.C.P.

The memorandums by Drs. McCulloch and Young may, in conjunction with the case described below, lead general practitioners to believe that pulmonary embolism following childbirth is perhaps not so very rare.

A perfectly healthy woman, aged 22 years, whom I had known all her life, was delivered of a healthy living female child on June 8th. On reaching the patient's house I found that the head was already distending the perineum, and the labour was over within forty minutes of my arrival. The perineum was not torn, the discharge at the time and on succeeding days was never profuse, the uterus behaved normally, the patient felt well and looked well. I intended to allow her up on the usual tenth day as her pulse and temperature remained uniformly normal up till the

ninth day. Between my visits on the ninth and tenth days the patient had complained to her attendant of a slight pain in the right thigh, but this had passed off within half an hour. On my visit on the tenth day I carefully examined the whole limb, but found no sign of any interference with the blood supply. As an extra precaution, however, I did not allow the patient to rise until the fifteenth day, by which time she was very anxious to get rid of me. On the fifteenth day she rose and remained up for almost an hour, feeling perfectly well and being actually unwilling to return to bed after what she was now considering an unduly prolonged rest. On the sixteenth day I saw her at mid-day; she was well in every respect and I allowed her to rise for two hours. At 2 p.m. she rose, and while in the act of dressing fell to the floor, and was lifted into bed, where I saw her at 2.20. I remained with her until she died at 3.45 p.m.

There could be no doubt of the diagnosis being pulmonary embolism. How many more cases within recent years could be quoted with this one and that given by Dr. Young?

Buckie.

J. A. DAWSON, M.B., Ch.B. Aberd.

#### FRACTURE OF METACARPAL BONE.

A YOUTH showed me his hand. The distal end of his right fifth metacarpal bone was swollen and painful. He gave no history of injury. From external examinations and an antero-posterior x-ray photograph it was decided that there was no fracture. The part was rested, though not splinted. The opinion formed was confirmed when, a few days later, the swelling took on the appearance of abscess formation. Poultices were applied and the "abscess" cleared up, although one day I thought it was going to point. The pain and swelling thereafter varied from day to day, and tuberculosis of the bone was thought of. Then antero-posterior and side-to-side x-ray photographs were taken, and it was seen that the bone was broken. There is now union with deformity, but a useful hand.

I was puzzled as to the appearance of abscess formation until I read in Scudder's *Treatment of Fractures* (p. 378) that in fractures of the metacarpals "a suppurative process may complicate recovery even when the fracture is not an open one."

CHARLES J. HILL AITKEN, M.D.

Kilnhurst, near Rotherham.

#### OEDEMA ARTEFACTUM.

NOTWITHSTANDING that a good deal of useful information is supplied in textbooks about dermatitis artefacta—and about graphodermia, which latter condition, as is well known to dermatologists, renders the production of a feigned eruption so easy—there occur cases so out of the common as to deserve record. Take, for example, this case about which I was recently asked to give my opinion:

A young girl presented on the back of each hand an almost symmetrically placed patch of oedema. After careful examination I came to the conclusion that the lesions were artificially produced by the mouth. The girl is the subject of graphodermia. The backs of the hands were puffy. The lesions were the size and shape of the half-opened mouth. The epidermis was slightly moist but otherwise quite normal. The abrupt margin of raised bleb-like centre was well defined, and around it was an area of reactionary redness, due to released pressure. This redness resembled the shape of a big letter "O"—that is, it was composed of two laterally placed crescents (lip-shaped) meeting in the longer diameter of the lesion. The swellings were disappearing rapidly to leave a normal condition of the skin. There could be no doubt whatever that the mouth had been used as a cupping instrument—that is, there had been suction by the mouth and pressure by the lips. No area of the body is more accessible to the mouth for such a purpose.

This case recalls to my mind a much more serious one of factitious oedema, which I saw many years ago.

I found a girl, well grown, aged 17, confined to bed with an enormously swollen left arm. When I took hold of the arm my fingers sank in. It was white, cold, and very heavy. There were several deep incisions oozing serum from pale pouging granulations. These incisions had been made for supposed phlegmonous erysipelas. Amputation of the limb had been talked of. On uncovering the shoulder I found a deep groove round the limb just below the deltoid. At several spots there were vertical streaks of subcutaneous haemorrhage. I asked for and procured the elastic band with which the constriction had been produced, called the girl's mother, and told her that, as self-mutilation was a crime, a policeman, not a surgeon, should be sent for, if the trick were repeated.

Not long afterwards the girl married, and in due course became a happy mother of healthy children.

London, W.1.

ALFRED EDDOWES, M.D.

## Reports of Societies.

### TUBERCULOSIS OF THE BLADDER AND KIDNEY.

At a meeting of the Section of Surgery of the Royal Academy of Medicine in Ireland, on October 29th, the President, Mr. ANDREW FULLERTON, read a paper on the investigation and treatment of tuberculous bladder and kidney, based on 150 personal cases.

Mr. Fullerton said that the existence of primary tuberculous disease of the bladder had been denied, but he had seen two cases of tuberculous bladder in which no evidence of disease in either kidney could be obtained. It had been stated that tuberculosis of the epididymis was an antecedent to tuberculosis of the kidney; he believed that the reverse process was the more probable sequence. He had been struck with the apparently healthy appearance of many patients with genito-urinary tuberculosis. Some had had antecedent disease elsewhere, such as tuberculous glands of the neck, pleurisy, hip-joint disease, spinal caries, and pulmonary tuberculosis. Some lived for many years, but others from frequency of micturition and loss of sleep soon became exhausted; in such cases a nightly rise of temperature was usual. Mr. Fullerton had found frequency of micturition the most prominent symptom; though remissions occurred, the course was progressive and eventually terminal haematuria supervened. Renal pain resembling renal colic might be the first symptom; it was present in about 50 per cent. of cases. In a very few cases severe renal haematuria had been noted, but more frequently the blood came from the bladder. The finding of tubercle bacilli in the urine was strong presumptive evidence of tuberculosis, but in a few cases the bacilli were found and a subsequent history entirely negated the diagnosis of urinary tuberculosis. If tubercle bacilli were present in the urine further investigation should be made. In males the testicles should be examined and rectal examination made to discover the condition of the prostate, the vesiculae, and the lower ends of the ureters. In females a thickened ureter might be discovered. The condition of the bladder and kidneys might be ascertained by cystoscopy, though sometimes this was difficult and not unattended by risk. Cystoscopic appearances varied. The affected ureteric orifice, at first showing slight redness or oedema or some change in shape, might be darker or more patulous. Later the "golf-hole" appearance might be seen. Systole and diastole might be abolished, the ureteric orifice advancing in inspiration and receding in expiration. In late cases ulceration had often been found. Grey tubercles, small papillomata, and small cysts were rare. The bladder wall might show general cystitis, isolated patches, a ringworm appearance, or typical shallow ulcers. The affected kidney could be detected, not only by ureteric meatoscopy, but by chromocystoscopy, and in most cases ureteric catheterization. Special stress was laid on unilateral diuresis and on tests for the specific gravity reaction. Slight albuminuria on the good side was disregarded after the diseased kidney had been removed. Where cystoscopy or ureteric catheterization was impossible the good ureter was exposed in the iliac region and catheterized through a small slit. Pyelography was useful as a confirmatory test, but was not devoid of risk.

Mr. Fullerton said that further experience had not altered his view that operation was the correct treatment; it convinced him that clinical cure was not impossible in certain cases. Medical treatment, including good hygienic surroundings, might cure a patient, but the outlook was much less satisfactory than that afforded by surgical treatment. He had removed seventy-one kidneys for tuberculosis with five deaths; the last thirty-six cases were without operative mortality. Details of several cases were given illustrating the excellent results obtained.

Sir ARTHUR BALL thought Mr. Fullerton had been fortunate in the number of cases of unilateral renal tuberculosis that he had met with. He himself believed that since the infection was generally haematogenous, both kidneys would be expected to be involved. He had found that in the early cases only one kidney was infected, but

in later cases both. If the infection was an embolic one this would account for the second kidney not being involved in early cases. He thought it was very hard to foretell the duration of life in cases of double renal infection. A patient of his own who developed typical tuberculous cystitis while home on leave went back to India, became completely free of the disease, and remained so for nine years. After that time the epididymis and the prostate became affected and renal colic set in, during which the patient passed no urine for about five hours, till the colic had ceased. He thought that the presence of typical-looking tubercles in the bladder was commonly met with, but was one of the later symptoms of the disease. In some cases cystoscopy was difficult and also risky.

Mr. SEYON PRINGLE dealt with the value of tuberculin in renal tuberculosis. In earlier days he had used tuberculin for many conditions, but now, as the result of experience, he confined its use almost entirely to the treatment of tuberculous glands and tuberculosis of the genito-urinary tract. He had come to look on it as an invaluable aid in the treatment of the latter condition, and ordered it with absolute confidence of beneficial results. The preparation used was either the new T.R. or B.E., commencing with very small doses, about 1/10,000 mg., and gradually increasing until in six or nine months' time the patient was getting as much as 1/100 mg. a week. He divided cases into three categories: (1) where the disease was definitely localized to one kidney and nephrectomy was the treatment of choice; (2) where the disease was bilateral and the patient could only be treated on general lines and by tuberculin; and (3) where at the first examination it was impossible to give a definite opinion as to the extent of the disease, either because a very irritable contracted bladder precluded a satisfactory cystoscopic examination, or because, although a good view might be obtained, the inflammation was so widespread that it could not be determined whether one or both kidneys were infected. He did not catheterize the ureters in these cases, as he believed the passage of a catheter through an infected bladder might possibly carry infection up a ureter previously non-infected, and so, in deciding on the condition of the kidney, he depended on the appearance of the ureteric openings, and on the time taken in the excretion of indigo-carmin. In treating cases of bilateral infection and doubtful cases he depended on tuberculin; in the former there was usually a definite improvement in frequency, pain, pyuria, and haematuria, and also in the general health. In a few such cases he had had exceptionally good results. In the doubtful cases improvement almost invariably followed, and, as the inflammation decreased, the patients could be relegated to either the first or second class. In some cases it had become apparent that only one kidney was infected and therefore nephrectomy had been safely advised. In others undoubted evidence was found of double infection, and these were condemned to a long course of tuberculin. Mr. Pringle gave notes of two illustrative cases, and added that he now confidently looked forward to improvement, and possibly even cure, in all but the most hopeless cases. In his opinion renal tuberculosis was benefited by tuberculin to an extent not experienced elsewhere in the body, and he regarded it as being of invaluable assistance as an adjunct to, or substitute for, operation.

Sir WILLIAM WHEELER remarked that polyuria on the affected side was an early diagnostic sign; although the specific gravity of the urine from the diseased kidney was low, the increasing quantity resulted in the delivery of the same amount of urea as from the healthy kidney in a given time. He had never seen or heard of a pathological specimen of a healed tuberculous kidney. He believed the disease to be essentially unilateral, and that bilateral infection was a very late phenomenon. He agreed that bilateral disease was consistent with apparent health after a number of years, and that tuberculin was probably one factor responsible for holding the pathological process in check. The passage of micro-organisms through the kidney and their presence in the urine was not always a sign of disease; bacilluria might occur in health. He thought that one of the most satisfactory cases to deal with was the patient with a large tuberculous kidney in which the ureter had become blocked. If the urine was found normal

in every respect by simple examination and the general health was good, the condition of the other kidney and its power to function was assured. He reminded the meeting that the President had been the first to emphasize the importance of unilateral diuresis as a constant sign of renal trouble.

Dr. L. L. CASSIDY referred to the difficulty of finding tubercle bacilli in the bladder, and said that in gynaecology not many cases of tuberculous cystitis were found, though watch was kept for it.

Sir WILLIAM TAYLOR said that once the diagnosis of tuberculosis had been made, if the disease was unilateral, the kidney should be taken out, but he agreed that tuberculin was valuable when both kidneys were involved. In a case he had treated both kidneys had been involved; tuberculin was given, and the patient now had three healthy children, there had been no recurrence, and it was fifteen years since the first attack. He would always use tuberculin when both kidneys were diseased and when it was doubtful whether the second kidney was involved or not.

Dr. F. S. BOURKE reported the case of a woman, aged 26, from whom the left kidney had been removed owing to tuberculosis eight months previously. Before operation she passed urine every hour, day and night. After the operation she obtained relief for three months, but the condition then became as bad as ever again, and the urine contained tubercle bacilli, pus, albumen, and *B. coli*. Caprokol had been tried and also tuberculin, but without benefit. Tuberculin even in small doses raised the temperature and caused pain. The patient was now having sodium morrhuate and ultra-violet rays, and only passed urine every two and a half hours.

Mr. H. S. MEADE, referring to a case cured by Mr. Fullerton in which the bladder was very rigid, said that he would group this among cases of submucous cystitis. He himself had had two cases similar to that one reported by Mr. Fullerton, but there had been no tubercle bacilli present, and the main symptom had been frequency of micturition. In one case it was impossible, even under spinal anaesthesia, to dilate the bladder more than to hold four ounces of urine. The patient was subsequently examined in London, and told that the condition was one of healed tuberculosis. He had found tuberculosis of the bladder more common than ulcers of the bladder. In cases that were definitely tuberculous, the catheter should not be passed up to a kidney that was functioning normally. He used indigo-carmin for testing, and the results from it were just as good as those with any other test.

Mr. FULLERTON, replying, said that he had removed the kidney in 71 cases in which the disease had been unilateral clinically. He never took away the kidney if pus was found on the other side. In addition to these 71 cases of which he had kept a record, he had removed tuberculous kidneys in a great many other cases, and this had confirmed the fact that in the large majority the disease was unilateral, though the absence of pus or tubercle bacilli was not positive proof of the integrity of a kidney. If the second kidney became involved it was not for some time, as he had seen cases going on for twelve years in which he had been satisfied that the other kidney was normal. Any examination of the bladder in a case of tuberculosis was attended with risk, but disasters did not happen very often in his experience. In emptying the bladder care must be taken that there was no pressure which would send up infected material into the kidney. Typical tubercles in the bladder were not very commonly found, and when definitely present the patients did not as a rule do very well. Ulceration might not be produced by tubercle bacilli but by their toxins. In Belfast the results obtained in these cases by the injection of tuberculin had not been very good. The thickened ureter in cases of tuberculosis was due to inflammatory fibrosis involving the mucous membrane. Where there had been hypertrophy of the bladder, the kidney on the opposite side became dilated because of the difficulty in entering the bladder. Unilateral diuresis was not mentioned in any textbook, and yet this condition was certain to be found in cases of tuberculous disease even in the very earliest stages, and

was, indeed, a way by which it was possible to diagnose a tuberculous condition. He himself did not depend on nephrectomy in cases of infection of the prostate, and thought it difficult to assess the value of nephrectomy against tuberculin in their treatment. When one kidney was sound, and yet the other kidney did not clear up, mild irrigation might be tried. He had tried indigo-carmin and found it useful, but it was necessary to get very accurate information about the kidneys; this could not be obtained by colour tests, since staining by pus or blood was likely to occur.

## SPASTIC PARALYSIS IN CHILDREN.

A MEETING of the Manchester Medical Society was held on November 3rd, with Dr. ALFRED A. MUMFORD in the chair; a discussion on spastic paralysis in children was opened by Dr. JOHN F. WARD.

Dr. Ward said that spasticity was difficult to define, but signified an increase of muscle tone, and was an indication of an upper neuron lesion. Such lesion explained easily the loss of voluntary power of muscles supplied by the affected nerves. Associated with spastic paralysis in children more frequently than adults were athetosis, choreiform movements, and perverse movements; these were explained by the unrestrained activity of extra-pyramidal tract owing to a pyramidal lesion. There had been much recent discussion as to the cause and control of muscle "tone," called "postural contraction" by Sherrington. It was certainly dependent upon the afferent impulses forming part of a reflex arc because division of the posterior nerve roots affected it. Tone was also influenced by the cerebellum, the corpus striatum, and, according to the work of the late Professor Hunter of Sydney, by the sympathetic nervous system. The following varieties of spastic paralysis in children were known: a diplegia group; a paraplegia group, including cases due to the same cause as that of diplegia, family and hereditary paraplegia, and paraplegia due to lesions of spinal cord and its membranes; hemiplegia; amaurotic family idiocy. The chief clinical manifestations of diplegia were spasticity of the legs, with adductor spasm, and often unrecognized until the child was several months old; some mental defect was present in most cases, but very variable in degree. The blindness in some cases was either cortical or due to optic atrophy. Convulsions might occur, but not so frequently as in hemiplegia; involuntary movements were also less common. There was a tendency to some improvement in a large proportion of cases. The two principal schools of opinion regarding etiology related it with intracranial haemorrhage or injury, and primary neuron degeneration. Little had believed asphyxia was the cause; later opinions assigned it to meningeal haemorrhage (McNutt, Gowers, and Osler), prematurity (Brissaud), and intrauterine degeneration of neurons (Freund and, later, Collier). In 60 per cent. of cases it was associated with abnormal labour, whether difficult labour, asphyxia, prematurity, or precipitancy. The work of Herbert Spencer, Eardley Holland, and others showed the great frequency of intracranial haemorrhage in still-born infants and those dying shortly after birth; injury and asphyxia were frequently combined in difficult deliveries. The haemorrhage was chiefly intradural and most frequently diffuse; it might be only petechial. Many patients died soon, but those that recovered might not show evidence of involvement of pyramidal tracts for some months because the pyramidal tracts were developed later. Necropsy evidence of diplegia cases supported Collier's view, but Schwartz had shown that atrophic sclerosis might follow haemorrhage. Syphilis was not an important cause; the Wassermann reaction was negative in most cases, and other symptoms of congenital syphilis were absent. Infantile hemiplegia was probably quite different pathologically in most cases. The onset was most frequently later than diplegia, and was most common between the ages of six months and two years. Convulsions and febrile disturbances occurred at the beginning of most cases; the convulsions might be due to the same cause as the hemi-

plegia, but possibly hemiplegia might arise as a vascular lesion owing to the congestion during the convulsion. There was often some history of infectious disease shortly before the onset. The cases might be due to vascular lesions, atrophy or sclerosis, or porencephalus; atrophy and sclerosis were probably sequels of encephalitis. There was some indication that this was a polio-encephalitis due to the same organism as poliomyelitis, but the evidence was not complete; "encephalitis" was a rather loose term. Treatment of spastic paralysis might be non-operative, including massage and re-education, or operative. Re-education was the most important; massage might soothe hyper-tonic muscles, but its effect could only be very transitory. Electrical treatment was absolutely contraindicated. Operative treatment consisted of division of the posterior nerve roots (Förster's operation); operations on peripheral nerves (Stöffel), tenotomy, and sympathetic rami-sectomy (Hunter and Royle).

Mr. E. S. BRENTNALL dealt with the principles governing the treatment of the spasticity of childhood. He emphasized the importance, and in some cases the difficulty, of forming at the outset a fair estimate of the patient's educability. In very young children the treatment had to be left largely to the parents; it should consist of simple stretching of the tight structures and elementary postural training. The use of a foot splint during sleep was essential, but prolonged immobilization and splinting were undesirable. Activity and its educative results were of the greatest importance to these children. In older patients treatment should consist of physical training, and should aim at developing the sense of balance and co-ordination of the child. Both physical and mental improvement could be anticipated in patients who were educable. Operative treatment was directed almost entirely to the relief of contractures; it should only be undertaken in children with a fair degree of educability, and not before promising efforts to stand and walk could be made. The speaker insisted that operative treatment in itself did not improve the sense of balance, and might interfere with it if the child was immobilized for long. The most useful methods adopted were the division, lengthening, and transplantation of tendons, and the Stöffel operation. Different methods would be found necessary in different parts of the limbs. In the case of the lower limb the operative treatment of suitable cases could be expected to produce distinct improvement in gait and activity. In severe spastic affections of the hand he doubted whether any tendon operation or nerve section was of real benefit, or could restore any degree of functional capacity to the limb.

Professor STORFORD confined his remarks to the investigations into the sympathetic innervation of striated muscle, and reviewed the researches of Hunter, Royle, and others in this field. He submitted proof of the existence of the sympathetic supply of muscle by histological and experimental methods, and then proceeded to discuss the functional significance of the fibres reaching muscle from the autonomic nervous system. It was pointed out that although the theory with regard to muscle tone propounded by Hunter and Royle had been severely criticized, their experimental results, and particularly those on the sea-gull, demanded further consideration and research. There was evidence from their work and that of others that sympathetic denervation had an effect upon muscular activity, and it was necessary to investigate fully what that effect was. It might be, as had been suggested, an indirect effect; the researches of Orbelli on the influence of the sympathetic upon fatigue were significant and might direct them to a correct interpretation of the experimental findings. Professor Storford also called attention to the fact that several surgeons who had considered the results of the operation of ramisection to be of no practical value had admitted that some effect had been produced upon muscular activity in a proportion of the cases. There was a risk of confusing the two problems: the interpretation of the experimental findings and their possible clinical application. Failure to obtain a result of practical value after ramisection did not relieve them of the duty of following up the experimental researches. For the immediate future it would be wiser probably to confine attention

to a careful analysis of the effects of sympathetic denervation, and a review of the present position seemed to justify the belief that this might lead to far-reaching results.

### DIAGNOSIS AND TREATMENT OF COLITIS.

At a meeting of the Section of Medicine of the Royal Society of Medicine on November 23rd Dr. A. F. HURST opened a discussion on the diagnosis and treatment of colitis.

Dr. Hurst said that a diagnosis of colitis should never be made until thorough investigation had shown that inflammation of the colon—nothing less and nothing more—was present. Examination of the stools was more important than consideration of the symptoms, which were not characteristic. Each stool passed on two or three consecutive days should be inspected by the clinician, in addition to the microscopical and bacteriological investigations made by the pathologist. The stools must be natural, and not obtained after an aperient or an enema. In the colon mucus was normally secreted in order to protect the mucous membrane from mechanical and chemical irritants, and, consequently, hard faeces were likely to be coated with it. Since most aperients acted by irritating the mucous membrane of the bowel, it was natural that, unless the dose was very small, the soft or liquid stools to which they gave rise should often contain mucus, secreted with the object of diluting the chemical irritant and so protecting the mucous membrane from damage. A similar response frequently occurred after injecting fluid into the bowel. The old custom, still followed in some spas, of sending every patient for a trial Plombières douche if mucus was found in the ejected fluid, and diagnosing colitis as the cause of the rheumatism, eczema, or neurasthenia for which the patient had sought treatment, had no scientific foundation, because many healthy colons responded to the abnormal stimulation of the douche by secreting mucus, even though the secretion gradually diminished during the "cure," as the mucous membrane became accustomed to the treatment. Whenever possible Dr. Hurst examined patients with the sigmoidoscope without any preparation by aperients or lavage, which caused the mucous membrane to be slightly redder than usual and excess of mucus to be present, even though nothing more irritating than normal saline solution was used for the douche. The temporary congestion and the secretion of mucus under these conditions were the natural response to the irritant and were not signs of colitis. The mucus secreted with hard faeces and after the use of aperients or enemas contained no pus cells, no red corpuscles, and no excess of broken-down epithelial cells; evidence of inflammation was entirely lacking.

In the condition badly described as muco-membranous colitis, shreds or large membranes of mucus were excreted with hard faeces. Dr. Hurst had never seen the slightest sign of inflammation in patients with this condition, unless they had been treated with irritating douches. Nearly twenty years ago he had suggested that this condition was strictly analogous with asthma, and he still thought that the analogy held good. In asthma over-activity of the vagus led to spasm of the bronchial muscles and excessive secretion of mucus by the bronchial mucous membrane. Owing to the spasm the mucus was retained long enough to coagulate, and as it was slowly extruded along the spiral bronchi it was moulded into the characteristic Curschmann's spirals. In uncomplicated cases there was no bronchitis, and the mucus contained no pus cells or albumin; the secretion ceased abruptly when the spasm relaxed at the end of an attack, whether this occurred spontaneously or after an injection of adrenaline. In the colon the spasm and over-secretion of mucus, which had been shown experimentally to occur on stimulation of the pelvic nerves, were due to similar nervous influences; the mucus, which contained no albumin and no pus cells, was retained owing to the spasm, and was coagulated by a ferment, mucinase, which Roger had isolated from both the bronchial and intestinal mucous membrane. Just as asthma might be complicated by bronchitis as a result of treatment by irritating inhalations, so muco-membranous

colic, as it should be called, might be complicated by a mild form of true colitis as a result of daily irritation by injudicious local treatment.

In true colitis the mucus always contained pus cells, and in the severe forms small quantities of pure pus could often be recognized in the stools. The presence of blood recognizable with the naked eye generally indicated the presence of ulceration, but smaller quantities might be present in acute colitis without actual ulceration. When the source of blood and pus in the stools was the inflamed mucous membrane of the colon, the stools were always soft and generally liquid. In the typical stool of ulcerative colitis isolated patches of liquid faeces, mucus, pus, and blood could generally be recognized, in addition to muco-pus and pus stained with blood. The presence of solid fragments of faeces in such a stool would point strongly to the presence of a growth. When blood was passed alone or on the surface of lumps of solid faeces, together, perhaps, with a little mucus or muco-pus, colitis was certainly not the cause, and a local source in the anal canal or rectum should be suspected.

In most cases the bacterial abnormality in ulcerative colitis was not due to the infection, but to the fluid nature of the stools and the presence of excess of soluble protein, blood, and pus, which formed a culture medium especially favourable for the growth of certain bacteria at the expense of others. Dr. Hurst thought there was no conclusive evidence in favour of any particular organism in the stools being the cause of the colitis. He had been so impressed in 1921 with the resemblance between the appearance of the colon seen with the sigmoidoscope in bacillary dysentery and in sporadic ulcerative colitis that he had revived the suggestion made by Saundby in 1906 and Hawkins in 1909 that the latter might also be due to infection with the *B. dysenteriae*, but in no case had the organism been isolated from the stools or from swabs taken directly from the ulcers through the sigmoidoscope, and in no case had the patient's blood agglutinated any of the known strains of *B. dysenteriae*. Dudgeon, however, had isolated the Flexner bacillus from material obtained from the surface of an ulcer through a sigmoidoscope in two cases. In 1924 Barger had isolated a diplococcus from swabs taken through a proctoscope from the ulcers in 80 per cent. of 68 cases of ulcerative colitis, but in only 1 out of 20 healthy patients. Intravenous injections of the diplococcus had produced similar lesions in rabbits and dogs. In a few cases the same organism was isolated from apical dental abscesses and from infected tonsils in patients suffering from the disease. Dr. T. Houston of Belfast had recently isolated a similar organism, but he was not yet convinced that Barger was correct in regarding it as the specific infective agent in sporadic ulcerative colitis. There was some doubt whether the ulcerative colitis from which Barger had isolated his diplococcus was the same disease as that in England. The sigmoidoscope should be considered as much within the province of the physician as the ophthalmoscope. Unfortunately, however, it was still often looked upon as a surgical instrument, with the result that numerous cases of cancer, which could not be recognized without its aid, were diagnosed too late, and a totally wrong conception of colitis was still widely prevalent. Ulcerative colitis could be recognized at the first glance through the sigmoidoscope, but its appearance was indistinguishable from that of bacillary dysentery. Amoebic dysentery presented a quite distinctive picture. When the mucous membrane of the rectum and pelvic colon was healthy, ulcerative colitis could be excluded, as the disease seemed always to begin in the most distal segment of the colon and to persist there longer than in any other part. When, therefore, stools containing blood and pus were passed by a patient in whom the sigmoidoscope had revealed no evidence of ulcerative colitis a growth of the colon was almost certainly present; if situated within ten inches of the anus it should be recognizable with the sigmoidoscope, even if it could not be felt by either rectal or abdominal examination.

When the sigmoidoscope revealed nothing abnormal and the symptoms pointed to the presence of some disease of the colon a barium enema should be given. By this means alone was it possible to recognize diverticulitis, a com-

paratively common disease, which generally involved the iliac and pelvic colon, and which was formerly almost invariably mistaken for either a new growth or colitis; it was, moreover, the only common cause of pericolicitis sinistra. An opaque enema also often showed the presence of a growth at a stage when it was still, impalpable and caused no delay in the transit of an opaque meal. An x-ray examination after an opaque enema should always be made in long-standing cases of ulcerative colitis which were not responding satisfactorily to treatment, as this might be due to the development of a stricture, the exact position and extent of which could be recognized in no other way. By this means the need for a short-circuiting operation had been discovered in two of his cases, although there was nothing in the symptoms to suggest that obstruction was developing. The extent of the ulcerative process in the earlier stages could also be recognized with the x rays after an opaque meal by the disappearance of the normal haustration and the mottled appearance of the shadow.

The high recovery rate following improved methods of treatment had resulted in the occasional development of late complications, which were formerly rare or unknown. Thus the autopsy records of the London hospitals for the twenty-five years ending in 1908 did not contain a single example of stricture following ulcerative colitis. Dr. Hurst had watched this develop in four cases; in two the strictures, which were multiple, were so severe that short-circuiting operations had to be performed before complete recovery could occur. He had also on three occasions watched the development of polypi as the ulceration healed. In a case of polyposis of the colon now under observation there was a long history pointing to a similar origin, and the polypi were still accompanied by severe colitis. It would probably be discovered that most cases of polyposis of the colon originated during the healing of ulcerative colitis. As the polypi showed a definite tendency to become malignant, an intermediate stage of polypus formation was the probable explanation of the development of a growth of the pelvic colon two years after complete recovery from ulcerative colitis in one of his pre-war patients and of cancer of the rectum following chronic dysentery in two others. In one of his cases innumerable small polypi had developed by the time the ulcers had healed; the stools were normal, and the patient felt perfectly well. All the polypi disappeared as a result of treatment with deep x rays.

In spite of the complications described most cases of colitis healed completely, healthy mucous membrane developing where at one time confluent ulceration was present. There was often much scarring, but with a magnifying eye-piece the sigmoidoscope showed that this was situated in the submucous tissue, where widespread white scars might alternate with deep red patches of dilated and sometimes stellate blood vessels; the mouths of new-formed crypts of Lieberkuhn could be seen to be evenly distributed over the whole surface of the mucous membrane. Dr. Hurst had recently had an opportunity of observing this condition four years after recovery from an exceptionally severe attack of ulcerative colitis which had lasted for three years.

#### Treatment.

The patient should be kept in bed until the sigmoidoscope showed complete recovery. As this might require many months a greatly restricted diet, such as one of milk and milk foods, was likely to lead to anaemia and other undesirable complications, which could be avoided by a generous mixed diet, from which everything leaving any solid residue had been removed. When much blood had been lost transfusion was of great value, not only in combating the anaemia, but also apparently by directly increasing the patient's power of overcoming the infection.

In 1919, in the belief that the disease was really an aberrant form of bacillary dysentery, Dr. Hurst had tried the effect of the intravenous injection of large doses of polyvalent antidysenteric serum. In the first case the result was little short of miraculous; a young man, who was almost moribund after being very ill for over a year, and in whom no improvement had followed an appendicectomy, recovered completely in a fortnight. Five days after the first injection the sigmoidoscope showed that the innumerable ulcers seen a few days before had vanished,

and nine days later the appearance of the mucous membrane was absolutely normal. In the eight years which had since elapsed he had had no recurrence. Since 1919 Dr. Hurst had used antidyenteric serum in every case, often with excellent results, though occasionally with little or none. He realized that the treatment might really be non-specific and nothing more than a form of protein shock, although in one case it had proved very effective after a series of injections of ordinary horse serum had failed. The dose of serum he now used was 40, 60, 80, and 100 c.c.m. injected intravenously on successive days, and then 100 c.c.m. for a few additional days. The reaction was occasionally somewhat alarming, but it was never really dangerous. Vaccine treatment did not seem to have any definite influence on the course of the disease. The persistent ulceration presented the chief difficulty in treatment, and it was far from clear what effect the vaccine could have if such ulcers persisted after a course of inoculation. Such infective foci as teeth with apical abscesses and inflamed tonsils should be removed, though severe local reaction had been known to follow the operation. Local treatment of the colon was undoubtedly of use, and Dr. Hurst generally used tannic acid (grs. i or ii to 1 oz.). It was most important that the fluid should be introduced through a soft catheter, which should not be passed more than an inch beyond the anus, as otherwise the rectal mucous membrane was likely to be injured. He gave half an ounce of charcoal and kaolin two or three times a day in the hope that they would absorb toxins; the former certainly absorbed gas, and so relieved colic, and it also deodorized the stools. There was no evidence that any so-called intestinal antiseptic exerted any action in the colon when given by the mouth.

It was of the utmost importance that the stools should not be allowed to get hard during convalescence, and therefore a saline aperient or paraffin should be taken regularly; the former might also reduce the frequency of defaecation in the early stages, and in this way might help to give the patient a less disturbed night. Every patient who had ever had ulcerative colitis should for the rest of his life keep his stools soft and should avoid all food leaving any solid fragments which could irritate the mucous membrane of the colon. The danger of relapse was, however, largely due to the fact that patients were allowed to get up and discontinue treatment when they felt well and the stools looked normal, which was often many weeks before the sigmoidoscope showed recovery. Apart from an occasional short-circuiting operation to overcome the obstruction caused by the development of a stricture in the process of healing surgery was very rarely required, and the results of medical treatment in his series of cases compared very favourably with the statistics of appendicostomy.

The PRESIDENT (Dr. Hugh Thursfield) thought that Dr. Hurst's views on the minor importance of bacterial abnormality in ulcerative colitis applied also to nearly all the other intestinal conditions except such specific infections as dysentery and typhoid fever. The prevalent wild views of this causation needed correcting. He believed that infantile diarrhoea in the autumn was possibly dysenteric, and good results had followed the prompt administration of antidyenteric serums without waiting for a bacteriological report. Many lives had been saved in this way.

Dr. W. EDGECOMBE (Harrogate) believed that "mucocolonitis" was not a true colitis, but a colonic mucorrhoea; it was a neurosis occurring in psychasthenics, and was comparable with asthma. The patients formed a well known type at the spas, being querulous and with their attention fixed in a morbid way on their abdomens. The treatment included stopping aperients, ordinary diet without coarse fibrous vegetables, and colonic lavage on alternate days with twenty to thirty ounces of isotonic saline solution under low pressure and at a temperature of not less than 102° F.; two douches were given at each session. After the first session or two large quantities of old mucus came away, and the general progress of the patients was striking. After the douche an immersion bath was given and a subaqueous douche to the abdomen. Other treatment included massage, exercise, psychotherapy, and the administration of bromides, belladonna, and full

doses of the ammoniated tincture of valerian. The results were very good, but occasionally the treatment had to be repeated.

Professor L. S. DUDGEON mentioned the importance of taking swabs directly from the ulcers, and agreed with the views of Dr. Hurst as regards the bacteriology of ulcerative colitis. With the possible exception of the *B. mucosus capsulatus* and the haemolytic colon bacillus no bacteria were concerned, and he denied that streptococci could be incriminated. The prevalent therapeutic intestinal bacteriology reminded him forcibly of the practices of Chinese medicine. He had seen two cases of ulcerative colitis in which there was a very high blood agglutination titre for the Shiga bacillus, though there was no other evidence of such infection. He could not understand how the serum treatment could be effective.

Dr. J. A. RYLE had seen about ten patients treated with serum who had improved very much, but he agreed that it was difficult to explain the mechanism of this treatment.

### BRONCHIECTASIS.

At a meeting of the Medical Society of London on November 22nd, the President, Sir HUMPHRY ROLLESTON, in the chair, there was a discussion on recent advances in the diagnosis and treatment of bronchiectasis.

Dr. CLIVE RIVIERE, in opening, attributed the protean character of bronchiectasis to the many causative factors. It might attack many or few bronchi, and these might be large or small, unilateral or bilateral, while the surrounding lung might be healthy, inflamed, or fibroid. The dilated tubes might be healthy, catarrhal, or the seat of great suppuration. For severe cases with suppuration new methods of treatment were urgently required. The recent advances in diagnosis comprised the use of the bronchoscope and of bismuth or lipiodol injections to render the diseased portion of the lungs opaque to x rays. In a large number of cases treatment by postural drainage and by the creosote chamber was quite successful. Only when these methods failed should other means be employed. The easiest of these was bronchoscopic treatment: aspiration, lavage, and removal of obstructions, granulations or strictures, through the bronchoscope. If "bronchial drainage" failed altogether other more radical measures should be considered. These included improvement of drainage, closure of cavities by collapse or compression of the lung, and extirpation of the diseased area. Only a small proportion of cases of bronchiectasis were suitable for surgery. Dr. Riviere dealt first with pneumotomy, but external drainage by such means was only useful when a single cavity or a "bronchiectatic abscess" was present. In a few cases where the cavities were capable of collapsing, artificial pneumothorax should be considered, but it was usually of little use, especially as adhesions were extremely common. There was also the danger of producing a pyo-pneumothorax. Such treatment was best for developing post-pneumonic cases in early life. Phrenic evulsion was only of use in strictly basal cases, especially on the right side, but it was even then only palliative at the best. Dealing next with thoracoplasty, the speaker stated that the older paravertebral thoracoplasty had done little good in cases of bronchiectasis. Recently Hedblom had introduced a more complete basal operation with greater success. Dr. Riviere thought, however, that this was a very severe measure to gain in most cases only a palliative effect. Ligation of the pulmonary artery had been tried for bronchiectasis, but without good results. Lobectomy or "cautery lobectomy" was a method of removal of a lung or lobe of a lung. It had usually been associated with a very high mortality, but more recently Evarts Graham had urged the use of the cautery for lobectomy, whereby the diseased area was destroyed piecemeal with the actual cautery. During the process the diseased bronchi were cut through and massive drainage was thus obtained. At the end bronchial fistulae were left, but these as a rule closed spontaneously at a later date. Air embolism and haemorrhage were the main dangers encountered. Of thirty-one patients of Graham's series 55 per cent. were reported cured and 13 per cent. improved, while the

mortality was 22 per cent., but most of these were cases of lung abscess, and the mortality of the operation in bronchiectasis would probably be much lower. Important recent work had shown how large a part aspiration of septic mouth secretions, of vomit, and of various extraneous bodies during anaesthesia, especially for operations on the throat and nose, played in the production of suppurative processes in the bronchial tract. Only by keeping the head downwards until the patient had regained his cough reflex could such accidents be avoided. Dr. Riviere referred to the valuable team work at the present time of the "Association of Thoracic Surgery" in America, and added that an annual congress devoted to chest diseases as a whole, and including physicians, surgeons, laryngologists, radiologists, and anaesthetists, would do more than anything else to forward this branch of medical work in this country.

Mr. J. E. H. ROBERTS thought that the surgery of pulmonary infections was in the position of abdominal surgery thirty or forty years ago. Cases were not seen by the surgeon until the larger bronchi were affected and the patients were enfeebled by chronic toxæmia, hæmorrhage, and even amyloid disease. He hoped that by closer co-operation of physicians and surgeons it might be possible to treat cases at an earlier stage. Diagnosis was the province of the physician, and it was often difficult, especially in affections of the upper lobes. In cases of swallowed foreign body or of new growth of the lung obstructing a bronchus diagnosis was often impossible for a long time; he mentioned one case in which a swallowed collar-stud had been present for twelve years. There were to-day two methods of exact diagnosis. Direct bronchoscopy was most useful, and probably when more and more cases came to the surgeon the need for a general anaesthetic, usually demanded in this country, would disappear. The more recent advance was due to the work of French colleagues, in particular Dr. Armand-Delille, and consisted in the injection of substances into the bronchi which were opaque to x rays. There were three methods of using lipiodol, the substance generally employed: by injection through a bronchoscope, by injection through a long tube with a metal end, introduced into the trachea and guided under x-ray examination, and by puncture of the crico-thyroid membrane. Mr. Roberts then described in detail the last method, dealing also with the dangers attached to its use. Coming to the question of treatment, he stated that except in the case of children medical treatment was purely palliative. By active medical treatment life could be rendered tolerable, but relapses were frequent, and no continuous employment was possible; there was also the risk of complications occurring, and the expectation of life was not great. Such considerations, said the speaker, rendered the more severe surgical procedures justifiable, but in every case a course of medical treatment should be tried first. Extensive drainage could only be of use if one or a few cavities were present, and it was therefore limited in its application. Collapsing operations were important; artificial pneumothorax was particularly of value in the early case, and it should be used as a routine in cases of pneumonia where the physical signs persisted. Suppuration was controlled and fibrosis limited, and the good results could be made permanent by some form of thoracoplasty. Phrenic evulsion was sometimes useful as a preliminary to other surgical procedures; it rarely sufficed by itself. Thoracoplasty gave the best results when the lower lobe was affected. Removal of ribs should be free; paravertebral resection was not enough, and anterior resection or complete decostalization should be performed in stages. There were two classes of case in which this operation gave beneficial results: those already benefited by a preliminary artificial pneumothorax, and those in which a great degree of contraction of the affected lung had occurred. Mr. Roberts then quoted cases to illustrate his remarks. He concluded by describing lobectomy and cautery lobectomy, and pleaded for earlier co-operation between physician and surgeon so that collapsing operations could be employed in the earlier stages.

Dr. P. F. ARMAND-DELILLE (Paris) said that after lipiodol injections patients certainly improved, but they usually relapsed. He had succeeded in doing artificial

pneumothorax in some cases, and in one case he had performed a bilateral pneumothorax. He raised the question of the possibility of bilateral thoracoplasty operations.

Dr. G. SCHRODER (Würtemberg) said that in Germany bronchiectasis was essentially a disease of childhood, and treatment should therefore be commenced early in life. Good results had been obtained by phrenic nerve evulsion in cases of bronchiectasis of the lower lobes. The results in thoracoplasty were also good; but the operations performed were more extensive than those already mentioned by previous speakers: full collapse was obtained by taking away all the ribs below the scapula on the affected side.

Dr. L. S. T. BURRELL agreed with Dr. Riviere as to the importance of medical treatment. He stated that a patient could be kept alive and healthy for the rest of his life by early medical treatment, and surgical intervention appeared to be only justified in the later and more desperate cases. It was important before beginning treatment to look carefully for the cause of the condition—as, for example, a foreign body, aneurysm, syphilis, or a neoplasm. The throat and sinuses should also be carefully examined. Attention to posture and the use of some form of creosote were very successful in many cases. If improvement did not follow and the trouble was localized to one lobe, artificial pneumothorax or washing out the cavities through the bronchoscope should be tried. This latter method gave good results, and in skilled hands was not painful or very inconvenient. It was found that the cavities thus treated tended to dry up eventually, and the patients were rendered comfortable and able to work. Surgical treatment should not be thought of until the bronchoscopic lavage had been tried. Dr. Burrell thought that thoracoplasty was not so successful as in pulmonary tuberculosis. He knew of one case in which the pulmonary artery had been tied successfully in 1916. Cautery pneumectomy appealed to him strongly as a satisfactory method.

Mr. TUDOR EDWARDS agreed that the value of lipiodol was well established, especially when surgical procedures were contemplated. He thought that artificial pneumothorax would not cure established cases of bronchiectasis, but if good results were obtained thoracoplasty should be employed to render the collapse permanent. He had performed phrenic evulsion in twenty patients with bronchiectasis, obtaining some improvement in almost every case. The cough was diminished, dyspnoea disappeared, and there was more complete evacuation of sputum. He had tried thoracoplasty in eleven patients with bronchiectasis with variable results; in four of these cases the condition of the patients was excellent. He had used cautery pneumectomy in one case, but was not very satisfied with the operation. He thought that cases of post-pneumonic fibrosis should be treated before dilatation of the bronchi was allowed to occur.

Dr. F. G. CHANDLER dealt with some of the difficulties in diagnosis. A patient might have a cough with morning expectoration for some years: evidence of bronchiectasis would be found in recurrent hæmoptysis, constant sticky râles in some part of the chest, and absence of tubercle bacilli from the sputum and faeces. The speaker then showed by slides how the differential diagnosis of the condition could be established by lipiodol. He pleaded for better treatment of unresolved pneumonia and for prolonged convalescence of cases after whooping-cough.

Sir PERCIVAL HARTLEY said that bronchiectasis appeared to be altering in its character, and the very severe cases were not common now. Preventive treatment was most important, especially after bronchopneumonia and whooping-cough. He thought that evulsion of the phrenic nerve was harmless, often did good, and should be used. Artificial pneumothorax might be tried in some cases, but he thought thoracoplasty should only be used in a very desperate case. Mr. ZACHARY COPE inquired about the expectation of life in certain cases which had been quoted as living for so many years after certain forms of treatment. Sir JOHN BROADBENT raised the question as to the way in which a bronchiectatic cavity might become infected. It appeared that such infection was more likely to occur after acute pneumonic processes than in cases of bronchiectasis due to pressure on a bronchus.

## Reviews.

### DISEASES OF THE HEART.

THE title *Facts on the Heart*<sup>1</sup> well expresses the contents of the book by Professor R. C. CABOT. The material round which it is written consists of 1,906 necropsies, covering all the cardio-vascular material in the 4,000 necropsies done at the Massachusetts General Hospital between the years 1896 and 1919; starting from the *post-mortem* diagnoses, the author has worked back to the clinical records. He modestly says that his own task has been the putting together and editing of material recorded by others, but it is essentially the editing which makes the book interesting and stimulating. It is not a textbook in the accepted sense of the word: the usual arrangement is departed from, the writings of the past are hardly referred to, and the whole text is a common-sense and realistic discussion and interpretation of the facts presented by various groups of cases during life and after death. The value of the book lies not so much in the new observations it contains as in its clear presentation of familiar material along modern lines. At the outset there is a statement to the effect that many terms used in discussing heart disease refer to imaginary conditions, and that we no longer need to consider and search for fatty degeneration, fatty overgrowth, brown atrophy, and myocarditis, or the senile heart. Clinical inquiry, the author remarks, is thus simplified and a correct diagnosis rendered easier; this promising start will perhaps dispose the reader to listen to what he has to say on other matters, and to withstand the shock of the question, "Does it exist?" with which the section on mitral regurgitation begins; the answer is that if it does it is extremely rare and that even then there are no physical signs by which it can be recognized, so that a diagnosis of mitral regurgitation without stenosis is never justified. Similarly a diagnosis of myocarditis is held never to be justified as a statement of the main cause of death, unless verified by necropsy. These opinions are not entirely new, but they are expressed with cogency and emphasis and will doubtless command attention. The cardiac condition most commonly recorded in this series is enlargement without valvular lesions, and the cause, though not established in all cases, is thought most probably to be hypertension, however produced. An interesting point made is that when once syphilitic aortitis becomes known it kills in most cases within two years from the first symptom—a prognosis of graver import than would be given in this country. While the discussions on the whole are concise and to the point, the numerous detailed clinical and *post-mortem* records tend to make tedious reading, especially with their "question and answer" additions: straightforward statements might have served the purpose equally well. The book offers much that is of interest and will fully repay careful digestion; it is clearly printed and contains numerous statistical tables; the various lesions are illustrated by photographs.

With Dr. G. F. LAIDLAW's translation of a book by Professor HENRI VAQUEZ, published under the title of *Diseases of the Heart*,<sup>2</sup> there is added yet another to the list of orthodox textbooks on this subject in the English language. It is a large book of over seven hundred closely printed pages, and is an excellent statement of French views from the days of Laennec and Potain to the present time. A detailed review of such a book is unnecessary; the main outlines of its arrangement and material do not differ from those of its predecessors. It is in this light perhaps that the volume is disappointing, for while the observations of recent workers in our own and other countries are freely referred to, yet there is little evidence that the spirit of dissatisfaction with traditional views expressed in these observations has to any considerable

extent influenced the beliefs of the author. Thus, though in speaking of auscultation it is remarked that the difficulty is still at the point where Potain left it—namely, to distinguish organic from extra-cardiac murmurs—yet in the chapter on mitral insufficiency there is no reference to the views of those who hold that it is doubtful whether such a clinical entity exists and that it is rarely if ever that such a diagnosis is justified. Again, the major syndromes of heart failure are considered under the headings of failure of the left ventricle, failure of the auricles, and failure of the right heart. On the other hand, in another place there is a good discussion on the causes of heart failure, and throughout the book the clinical pictures are faithfully presented. The closing chapters are devoted to the treatment of heart disease in general. It is of interest in this connexion to note that the author is of opinion that quinidine may be tried even in the presence of heart failure by taking the precaution to give a preliminary course of ouabain or digitalis. Lists of references are given at the close of the principal chapters, and there is a good index.

The *Manuel de Cardiologie Pratique*<sup>3</sup> by Professor SCHRUMPH-PIERON of the medical clinic of the Kasr-el-Aini Hospital at Cairo is a complementary volume to his *Diagnostic Cardiologique*, published about five years ago. In it he addressed more particularly the cardiologist who was interested in the newer graphic methods; the present handbook is prepared specially for students and practitioners, and in consequence has a more immediately practical bearing. The presentation of the subject in general follows stereotyped lines. After chapters dealing with anatomy, physiology, and physics of the circulatory apparatus the different methods of examination are explained in detail, more attention being paid to physical methods than to graphic records. In discussing diseases of the heart too much stress is laid on valvular lesions as such, and in many cases no mention is made of etiological factors in connexion with them. A special chapter is, however, devoted to syphilis, and some useful figures are presented. Thus of 417 cases of visceral syphilis in a series of 4,280 patients, 60 per cent. had cardio-vascular lesions, and of 992 patients in the same series who had cardio-vascular disease, 46.7 per cent. had syphilis of the heart or aorta. Angina pectoris and diseases of the blood vessels are also dealt with, and treatment is discussed in the closing chapter. The book will no doubt serve a useful purpose, and it gives the author's views in the lucid style characteristic of the best French writings. We do not, however, observe any outstanding merit which would make it likely to displace books on the same subject in our own language.

The second edition of *Modern Methods in the Diagnosis and Treatment of Heart Disease*,<sup>4</sup> by Dr. F. HEATHERLEY, has been increased in size, and the price has risen from 5s. to 8s. 6d. The author has added a chapter on infections, and one on blood pressure, largely derived from the results of French investigations. The appendix includes a form of instructions which has been found very useful at the Manchester heart clinic in securing the intelligent co-operation of patients suffering from functional disorders of the heart. This form of instructions has now been published separately as a pamphlet, which may be obtained from the publishers at the price of 3s. 4d. a dozen.

### BRAINS OF RATS AND MEN.

PROFESSOR C. J. HERRICK's book entitled *Brains of Rats and Men*<sup>5</sup> deals with the subject of the mechanism of control of animal behaviour and the light thrown upon it

<sup>1</sup> *Facts on the Heart*. By Richard C. Cabot, M.D. Philadelphia and London: W. B. Saunders Company. 1925. (Roy. 8vo, pp. 781; 163 figures. 3s. net.)

<sup>2</sup> *Diseases of the Heart*. By Dr. Henri Vaquez. Translated and edited by George F. Laidlaw, M.D. Introduction by William S. Thayer, M.D. F.R.C.P. (Hon.). Philadelphia and London: W. B. Saunders Company. 1925. (Roy. 8vo, pp. 743; 145 figures. 42s. net.)

<sup>3</sup> *Manuel de Cardiologie Pratique*. Par Professeur P. Schrumph-Pieron, Cairo. Paris: N. Maloine. 1925. (7 x 8½, pp. vii + 333; 67 figures, 1 plate. 28 fr.)

<sup>4</sup> *Modern Methods in the Diagnosis and Treatment of Heart Disease*. By Francis Heatherley, M.B., B.S. (Lond.), F.R.C.S. Second edition. London: Baillière, Tindall and Cox. 1925. (Extra post 8vo, pp. xii + 269. 8s. 6d. net.)

<sup>5</sup> *Brains of Rats and Men*. By C. Judson Herrick, Professor of Neurology, University of Chicago. Chicago: University of Chicago Press; London: Cambridge University Press. 1926. (Post 8vo, pp. xiii + 322; 53 figures. 15s. net.)

by the fundamental experiments of Lashley on learning-processes in rats. Among other experiments Lashley showed that rats would, after a certain number of trials, learn to press a pedal-board in order to open the door of their food-box. They would learn to do this even after removal of almost the whole of the cerebral cortex; but if the habit was acquired before removal of the cortex it was lost after the operation and had to be relearned. It appeared, therefore, that although the cortex played a part in the formation of new habits, its participation was not absolutely essential.

Professor Herrick addresses himself to the question of the function of the cortex in the light of these experiments. Setting aside the current methods of objective psychology, he proceeds on strictly biological lines, describing the gradually increasing complexity of cerebral mechanism, from the brains of fishes and amphibia upwards, and indicating its bearing on mental capacity. In the lower animals the greater part of the cortex is occupied by projection centres, each connected with some particular thalamic reflex apparatus—visual, somæsthetic, etc. Each centre is surrounded by a zone of associational fibres concerned with the correlation of the cortical centres. In an animal provided with a nervous mechanism of this kind, if the usual simple reflex resulting from stimulation does not result in a response adequate to the circumstances, nervous impulses pass over into the thalamus and cortex and a number of other behaviour-patterns are brought into play; if an adequate response should result from one of these, the re-activation of the corresponding behaviour-pattern is thereby facilitated and a habit is formed. This seems to be the nature of the learning-process in the rat. In higher brains the cortical associational zones are separated by secondary association centres, which are not dominated physiologically by any one system of projection fibres. With the elaboration of these centres, emancipated as they are from the domination of subcortical sensorimotor systems, a mechanism is available for the recombination of habitual behaviour-patterns in hitherto unexperienced ways; in other words, imagination becomes possible, and the animal acquires insight, not merely looking at a problem, but looking through it to the solution. Further, the associational centres are so organized that a similar structural change or cortical set may be preserved, even in those cases where a cortical association does not result in overt action; and reactivated cortical patterns (memories), knit in with the lower sensorimotor systems at the moment in action, serve as deciders of conduct.

In the rat the association centres are poorly represented and there is little evidence that the animal possesses anything in the nature of insight. In learning it has to trust to some behaviour-pattern chancing to be adequate to the occasion; it does not foresee the solution of the problem. That which is most characteristic of human cortical activity is a plasticity of organization which facilitates the formation of innumerable transient associational patterns which have no enduring quality. In advance of any overt act we think through many provisional solutions, discarding one after another until the right course is discovered. It is the capacity to do this that most sharply differentiates men from rats. Professor Herrick's work is an interesting piece of close reasoning.

#### MATERIA MEDICA FOR DENTISTS.

WE are impressed by the fact that a sixth edition of COLEMAN'S *Materia Medica for Dentists*,<sup>6</sup> which first appeared in 1914, has now been called for, and we take this as evidence of appreciation by a great number of students. Our opinion that students are collectively good judges of the merits of a textbook is confirmed by a perusal of the work. The descriptive notes on materials are neither unduly curtailed nor so much laboured as to make heavy reading, but are neatly expressive of the facts and adapted with good judgement to students' needs. Notes on pharmacology and therapeutics which are

appended to the description of drugs and chemicals convey a clear account of their properties. The pertinent facts of physiology are also summarized in illustration of principles of treatment; and toxicological data are given in ample detail regarding those substances which in overdoses exert untoward effects. The book appears to contain all that is needed to equip the practising dentist with adequate knowledge of the *materia medica* that he may have occasion to use.

#### DISEASES OF THE PROSTATE.

IN his *Traité des Maladies de la Prostate* Dr. GEORGES LUYs deals with the various diseases affecting the prostate and with modern methods of treatment. The author's name is particularly associated with direct-vision urethroscopy and cystoscopy, and with the treatment of enlargement of the prostate by means of diathermy; it is natural, therefore, that these subjects should take a prominent place in his book. Those who have departed from the routine practice of prostatectomy for all cases of enlargement and have advocated the use of less drastic methods in cases of minor enlargement have been subjected to considerable adverse criticism, and in the portion of his work devoted to the subject of *forage*, or removal of the obstructing portion of the prostate by means of diathermy applied through a posterior urethroscope, the author has dealt at length with the objections that have been brought against this method of treatment. Naturally he writes with the pen of an enthusiast, and it may be that his enthusiasm has carried him too far in the direction of advocating *forage* for some patients in whom total prostatectomy would be a more suitable operation. Unjust criticism is very apt to produce this reaction in those against whom the criticism is directed. However, although such a large portion of the book has been devoted to *forage*, the author has wisely obtained the collaboration of an exponent of total prostatectomy, and Dr. VICTOR PAUCHET has contributed the chapters on the surgical treatment of enlargement and of cancer. Dr. Pauchet is a partisan of the perineal route and, after describing the method employed by Young, deals with his own, which appears to be a combination of certain points from Young's and some other surgeons with that of Proust. This portion of the work has been very clearly written and, what is still more important, has been illustrated with such a profusion of diagrams that it is possible for the reader to follow each step in the perineal operation without even referring to the text.

In the section dealing with prostatitis, written by Dr. Luy's, the author advocates the use of a Frank's dilator, and states that this instrument (which in England is known as a Kollmann's) exactly fits the posterior urethra and allows of its dilatation. In our opinion, however, no instrument has yet been constructed that is capable of bringing an equal pressure to bear on the walls of so complicated a cavity as that of the prostatic urethra; in the hands of the average surgeon any form of mechanical dilator may do more harm than good when used in the prostatic urethra. It may be said, therefore, that the most noteworthy features of Dr. Luy's book are an apologia for endoscopic methods of treatment, a full account of the technique employed by the author, and excellent chapters on perineal prostatectomy and the surgical treatment of cancer by Victor Pauchet. The book contains much that is peculiar to the author, and will not therefore meet with general favour, but at a time when medical books are turned out in great profusion without any particular reason for their appearance, originality is a welcome quality. In his preface the author states that he has gone to considerable pains to ensure that the book should be well illustrated, and he has succeeded. It is a pleasure to read a book in which surgical technique can be followed so clearly by reference to the diagrams. It is by skilful use of line drawings rather than of half-tones that the greatest assistance is given to the reader, and the text of *Traité des Maladies de la Prostate* is excellently served in this respect.

<sup>6</sup> *Materia Medica for Dentists*. By Frank Coleman, M.C., L.R.C.P., M.R.C.S., L.D.S. Sixth edition. Oxford Medical Publications. London: Hafford, Oxford University Press. 1926. (Cr. 8vo, pp. xvi+348. 10s. 6d. net.)

<sup>7</sup> *Traité des Maladies de la Prostate*. Par Georges Luy's. Prostatites, tumeurs malignes, par Victor Pauchet. Paris: G. Doin, 1926. (67 x 91, pp. 680; 457 figures, 5 plates. 50 fr.)

## NOTES ON BOOKS.

IN volume vi of MELLOR's *Comprehensive Treatise on Inorganic and Theoretical Chemistry*<sup>1</sup> the subject of carbon is continued, the sections dealing with carbon dioxide, carbon sulphides, and related matters bringing the chapter to a conclusion. The cyanides are not touched on, academic authority having decreed that these belong to the subject of organic chemistry; a note by the author, however, conveys a hint that they may be discussed in a supplementary volume. The subject of silicon follows carbon in order of treatment here, as does the element in order of periodicity. It is concerned with a vast number of minerals and compounded silicates; though many of them possess only isolated points of interest, the pages present a wealth of information to the mineralogist, and there is much readable matter under the headings of the better known substances, such as talc and meerschaum. The latter, we are told, is used as a building stone in Spain and as a soap in the Moorish baths of Algeria. Ceramics, glass, hydraulic cement, and materials used in the arts furnish so much matter for discussion that nearly seven-eighths of the whole volume are devoted to the chemistry of silicon. The compilation has been done in the same satisfying manner that we have had occasion to eulogize in noticing preceding volumes of this edition.

If the dead languages are as dead in America as some people would like to make them in this country, then Mr. ARTHUR L. TATUM's little book *Prescription Notes*<sup>2</sup> is justified. For he tells the student how to write a prescription, the meaning of the Latin terms used, how *recipe* governs the accusative, that a portion of a drug is in the genitive case, and that orders to the pharmacist are given in the subjunctive mood. But directions for the patient must be written in English, says Mr. Tatum, so the cochlear of Celsus appears nowhere in the glossary. For the rest the student is given a few general rules about incompatibility, some weights and measures, the dosage of the more important drugs in the *United States Pharmacopoeia*, and many blank pages for recording prescriptions. "Verbatum" is, we presume, a misprint for the word coined from the dead language Mr. Tatum teaches.

*Folia Japonica Pharmacologica*<sup>3</sup> is a new journal containing papers on pharmacology from the Japanese laboratories. Most of them are in Japanese, and only a minority are in European languages, but summaries in German or English are given of the Japanese papers. Two volumes of about 400 pages have appeared during the past year—a fact which bears testimony to the activity with which research is being prosecuted in Japan. The papers are on a great variety of subjects, but a large proportion deal with the analysis of the action of drugs by the study of their effects upon isolated organs.

Following the practice of their previous edition of the animal parasites of man,<sup>4</sup> BRAUN and SEIFERT have divided what would have been an extremely heavy and cumbersome volume into two parts. The first or zoological part is by Dr. Max Braun, and has already been noticed in these columns (BRITISH MEDICAL JOURNAL, November 14th, 1925, p. 909); the second or clinical part is by Dr. Otto Seifert, and has just been published. It is a volume of 600 pages devoted entirely to a consideration of the clinical and therapeutical aspects of protozoology, helminthology, and entomology—eloquent testimony to the advance in our knowledge of the animal causes of disease. This volume has been considerably revised since the previous edition in 1920, but the new matter is mainly of German origin; the account of foreign work is sketchy and often incomplete. Some new chapters have been added; others have been considerably revised. The illustrations are few in number, and on the whole poor in quality. It is unfortunate that a volume which occupies such an important position in the standard literature of tropical medicine should not be better provided with clear and adequate drawings and photographs. In spite of these defects, Dr. Seifert still maintains the high standard of usefulness and the comprehensive encyclopaedic character of his book, and renders available for those who read German a useful synopsis and compendium of such diseases of man as are caused by animal parasites both in tropical and temperate countries.

<sup>1</sup> *A Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. vi. By J. W. Mellor, D.Sc. London and New York: Longmans, Green and Co., Ltd. (Roy. 8vo, pp. x + 1024; 203 figures. 13 5s. net.)

<sup>2</sup> *Prescription Notes*. By Arthur L. Tatum. Chicago, Illinois: University of Chicago Press; London: Cambridge University Press, 1926. (Fool 8vo, pp. 22, and many blank pages. 6s. 3d. net.)

<sup>3</sup> *Folia Japonica Pharmacologica*. Vol. I; Vol. II, Fasc. I, II, and III. Kyoto Imperial University: Pharmacological Institute.

<sup>4</sup> *Die Tierischen Parasiten des Menschen*. Bearbeitet von Dr. Max Braun und Dr. Otto Seifert. Zweite Teil. Klinik und Therapie der Tierischen Parasiten des Menschen. Von Dr. Otto Seifert. Dritte Auflage. Leipzig: C. Kabitzsch, 1925. (Sup. roy. 8vo, pp. vi + 574; 21 figures. M.27; bound, M.29.50.)

## IMPERIAL CANCER RESEARCH FUND.

AT a meeting of the General Committee of the Imperial Cancer Research Fund held on November 23rd, with the DUKE OF BEDFORD, President, in the chair, Sir HUMPHRY ROLLESTON, Bt., chairman of the Executive Committee, in moving the adoption of the annual report, including that of the director, Dr. J. A. Murray, said nothing was more striking than the way in which progress in scientific work was characterized by a series of successive periods of great activity, with periods of relative quiescence between. Each period of activity was started by some salient discovery or fruitful conception, the working out of which engaged for a longer or shorter time the energies of those employed in that field. He instanced the application of the spectro-scope to stellar astronomy by Huggins, the discovery of radio-activity, and, in the biological sciences, the rediscovery of Mendel's laws of heredity and also insect transmission of tropical protozoan diseases, the bacteriophage, and the discovery of hormones. The same might be said of the era opened up by Ehrlich's brilliant achievements in chemotherapeutics, and the isolation of insulin still more recently had started the wave of activity in the study of the physiology of carbohydrate metabolism and the therapeutics of diabetes which was in full career at the present time. Cancer research exhibited the same phenomenon in a striking manner. The first period was that following the discovery by Jensen and Borrel of the transplantability of the malignant growths of the mouse. Although there was a tendency for the achievements of that period to be overshadowed by more recent work, it should be recognized that the insight into the properties of cancer cells which was owed to Jensen and his successors had given a precision to conceptions of the cancer process as essentially a cell problem which dominated the attitude to all attempts to elucidate its causation to the present day. The work of this first period dealt with the cancer cell already fully developed and the attempts at explanation based on it of the etiology of the disease were in the nature of inferences, more or less happy. In the second period the interest shifted to the study of the conditions under which cancer arose in the individual primarily attacked. The work of Fibiger, Yamagiwa and Ichikawa, and Tsutsui gave the primary impetus to an enormous amount of work, which still continued, on the actual production of cancer anew, starting with normal animals. The part played by chronic irritation in the causation of cancer, the relation of the duration and intensity of the irritation to the time necessary for the effects to be produced, and the mutual reinforcement which different agencies give to each other, had put a rational, sequential faces on many of the features of the natural history of cancer which, till these investigations had been carried out, still appeared mysterious and capricious. Much remained to be done along these lines, and work proceeded in the laboratories of the Fund in continuation of the investigations mentioned in last year's report. If the interest and activity aroused were taken as an indication, the work of Gye and Barnard on cancer causation by ultramicroscopic microbes, published eighteen months ago, could be regarded as starting still a third period in cancer research. A number of papers had appeared in Europe and America, and, as was to be expected, agreement had not yet been reached. Both the facts and their interpretation were in dispute, and in these circumstances it was necessary to exercise patience and continue the investigations. Of the various lines of work bearing on the validity of Gye's conception at present in progress in the Fund's laboratories, that of Dr. Begg was furthest advanced. His results confirmed the existence of two factors, as advanced by Gye, in the successful transmission of these tumours.

Sir ANTHONY BOWLEY, Bt., seconded the motion to adopt the annual report, and this was carried unanimously.

Sir HUMPHRY ROLLESTON then moved that an annual general meeting be not held in future, with the understanding that the General Committee would be summoned to meet when there was business to transact, and that the annual report would be issued to the General Committee and to subscribers as heretofore. This was seconded by Sir FREDERICK ANDREWES and carried.

The PRESIDENT, after paying a tribute to the memory of Sir Henry Morris and expressing gratitude for the work he did for the Fund, said it was an experience common to all charitable institutions at the present time that the amount received from legacies and donations was declining, no doubt on account of the increased cost of living, continued pressure of taxation, and the very heavy death duties—a combination which left people but little margin to give for even such subjects so important to mankind as cancer research. A satisfactory point disclosed by examining the statement of receipts and expenditure was that the office expenses, including salaries, printing, stationery, and advertisements, worked out at less than 7 per cent. of the total expenditure. On behalf of the vice-presidents and other members of the General Committee, he expressed to the chairman and members of the Executive Committee, the subcommittees, and the honorary treasurer (Sir George Makins) their appreciation of their honorary services in the cause of the Fund.

A vote of thanks to the President was adopted on the motion of Sir JOHN ROSE BRADFORD, P.R.C.P.

### THE SCHOOL OF HYGIENE AND PUBLIC HEALTH OF THE JOHNS HOPKINS UNIVERSITY, BALTIMORE, U.S.A.

(Concluded from page 959.)

In our last issue we reported the opening of the new buildings of the School of Hygiene and Public Health at Baltimore, and gave an account of its general character, with a picture of the elevation. We now give an account of its departments and the manner in which they are housed; for the information on which it is founded we are indebted to Dr. Andrew Balfour, director of the London School of Hygiene and Tropical Medicine. We mentioned last week that Dr. Balfour, whose address at the opening ceremony was published in the *BRITISH MEDICAL JOURNAL* of October 30th, received the honorary degree of LL.D. from Johns Hopkins University. Dr. Balfour, on his way back, delivered an address at the scientific medical conference held at the University of Rochester, New York, on October 26th, and received from that university the honorary degree of D.Sc.

The general plan was to give a separate floor to each department and to place the administrative offices and the rooms for general purposes in the first floor and basement. This was the scheme which it was intended to carry out in the London school, but unfortunately it could not be realized in its entirety. Even at the Baltimore school there is an exception, for the department of public health administration shares the second floor with the department of epidemiology.

A special feature of the building is the arrangement for animal quarters. A separate elevator and a service stairway are provided so that animals, food, and supplies can be brought to each department without entering the main building. The animal quarters are built vertically in such a way that each department has access to its animals on its own floor. The animal rooms, while continuous externally with the rest of the wing, are separated internally by a wide air-shaft provided with double doors and a ventilating fan. Special extra provision has been made for a rat colony in the department of chemical hygiene. It is interesting to note that in the plans for the London school a somewhat similar provision has been made in the biochemical department of the chemical division. With this exception the quarters for the experimental animals have, in the case of the London school, been placed upon the roof, occupying two recessed floors, the fourth and fifth.

More reliance is placed on artificial ventilation in the Baltimore than in the London school, where, with the exception of the large lecture theatre, natural ventilation is the rule. To some extent this is no doubt explained in terms of the different shape of the two buildings. The school at Baltimore has some other features not seen in

the London building—as, for example, a large kitchen and serving and dining rooms in the basement; it has the advantage over the London school of drawing its steam heating and water supplies from a central plant. Hence there has been no need to provide boilers and furnaces in the basement, and much space has thereby been saved.

On the first floor the administrative offices, together with a rest room, locker room, and toilet for women students, occupy the front of the building. In the central wing, on the eastern side, is the main auditorium, with seats for 310. The north wing contains the general library and the librarian's office, while a similar room in the south wing, originally intended for a museum, is at present used as a lounge and reading room for students. This floor is connected with the basement and the upper stories by two fire-proof stairways and two passenger elevators. The first floor answers to the ground floor of the London school, and has much in common with it so far as the general lay-out goes, for in both are the administrative offices, student rooms, and a large lecture theatre. Here, however, the resemblance ceases, for in London the division of sanitary science and public health administration occupies this part of the school building, which contains also laboratories for the director, for sanitary engineering, and for tropical hygiene and pathology. In the London building the library, a very large and handsome room, runs nearly the whole length of the front on the first floor. It is a much more important feature than the library in the Johns Hopkins School, where, however, the arrangement is temporary, as there is a scheme to concentrate all the library facilities of the medical centre in a building adjacent to the school of hygiene.

#### *Public Health Administration and Epidemiology.*

The second floor at Baltimore is shared by the department of public health administration and that of epidemiology. The former does not require elaborate or special equipment, and accordingly the rooms assigned are, for the most part, offices and classrooms. The same is true of the corresponding division in the London school. At Baltimore certain rooms along the west front are occupied by the office of administrative information of the United States Public Health Service, and a somewhat similar arrangement holds good at the London school, where, on the first floor, a series of rooms is allotted to the Bureau of Hygiene and Tropical Diseases, at present an activity of the Colonial Office under the direction of Dr. A. G. Bagshawe. At Baltimore a room of the second floor is assigned to the local office of Shellfish Sanitation of the Public Health Service. Of the remaining rooms in this department mention may be made of that used for the preparation of the large amount of mimeographed material employed for teaching purposes, the seminar room for advanced classes, and the workroom for special students. Much of the teaching of this department is carried on by field demonstrations and conferences.

The department of epidemiology, which also requires no elaborate arrangements for its intramural work, occupies a little more than half of the floor and shares a lecture room and seminar room with the department of public health administration. In addition to general office rooms and a departmental library, there is a room for mimeograph work and the filing of records, a storeroom and a dark-room for photographic work, which, however, is at present done by commercial photographers. In the south-west wing is the general students' laboratory, a large, well lighted and well ventilated room equipped for a class of at least forty. Each student has his own work table, and is supplied with a ten-inch slide rule to assist him in his calculations. There is a laboratory for special students, where Monroe calculating machines and a drafting table are available. A seminar room permits of informal conferences with small groups of students.

At the London school, where the teaching of epidemiology is combined with instruction in vital statistics, the special provision, though not so extensive as at Baltimore, is on very similar lines, but both at London and Baltimore it is recognized that epidemiology, properly defined in a broad sense, is a science much too comprehensive to be taught in any single department of the school. Hence, in that bearing its name, the consideration will be limited to certain aspects of the subject, some of which are best studied in the field.

#### *Biometry and Vital Statistics.*

The department of biometry and vital statistics fills the whole of the third floor, and it would seem that the large amount of space at its disposal is somewhat disproportionate, considering, for example, that the large department of medical zoology, embracing a number of highly important subjects, possesses similar accommodation, if we exclude the section of filterable viruses, which does not really belong to it. The strong position

of biometry and vital statistics at Baltimore is doubtless traceable to the influence of Dr. Raymond Pearl, formerly the director of this department and now head of the Institute of Biological Research, with which his old department is in close association.

The department has a general lecture room, a general student laboratory with its seminar room, staff offices, the graduate student library, the departmental library, the general laboratory rooms, and storage rooms. The department is specially well equipped, containing a complete Hollerith outfit for analysing statistical data by the use of punched cards, a drafting and photographic section with a photostat machine for duplicating work, and a supply of drawing instruments, together with planimeter and integrator. Practically all types of modern computing and adding machines are in use in the department, and each student has a computing machine.

One room is fitted up as a probability laboratory and contains a sampling machine designed and built by the department. The departmental library is a special feature, for it collects and stores the raw data in the field of vital statistics. At the London school good provision has been made for the study of vital statistics, at least by the ordinary D.P.H. student. With facilities available at the Galton Laboratories of University College there was no need to have such a large and elaborate department as the Johns Hopkins school can boast.

#### *Medical Zoology.*

The fourth floor at Baltimore corresponds to the third floor of the London school, for it houses the department of medical zoology, including protozoology, helminthology, and medical entomology. A large room consisting of four units is used as a lecture room and laboratory for courses in these subjects and in parasitology and filterable viruses; it is used also for the weekly meetings of the Research Club in Medical Zoology and for various special meetings. A two-unit room adjoining the students' laboratory serves as a students' reading room, and also for seminary meetings and also for the weekly luncheons of the department; in it are the Samuel Taylor Darling Library and the departmental library. A number of other rooms for general use by both students and investigators include a refrigerator room, a centrifuge room, and rooms for instruments, glassware, chemicals, and technical assistants.

A group of seven rooms is provided for protozoology, and a similar group of eight rooms for helminthology; there are three rooms for medical entomology, and one for filterable viruses. A large three-unit room is used for students carrying on special work in medical zoology. This division of the floor space enables the students of each subject to maintain constant relations with each other, and supplies a common meeting place in the seminary room, students' laboratory, and general supply rooms.

There is a general resemblance to the arrangements at the London school, where, however, the general students' laboratory is much larger, as all the students studying tropical medicine have to be accommodated, and provision is being made for an insectarium and an aquarium.

#### *Bacteriology.*

The department of bacteriology, which is on the fifth floor at Baltimore, has been organized along somewhat special lines. A large media preparation division has been established; though expensive to run, it saves both time and effort on the part of instructors and students. There is a teaching laboratory easily accommodating forty students, and in it courses in what are called sanitary bacteriology and public health bacteriology are given. The former embraces the bacteriological examination of air, soil, water, sewage, milk and other foods, while the latter is concerned with the study and identification of the pathogenic organisms responsible for disease in man and the differentiation of the pathogenic bacteria producing disease in man and animals from similar organisms which play no such part. A smaller laboratory is devoted to work on food bacteriology and spirochaetology, and graduate students have a room to themselves. There is also a small laboratory for the chemical work which is necessary, from time to time, in any bacteriological department. There are rooms in addition for single workers and for two workers, and a seminary or lecture room, shared with the department of immunology.

#### *Immunology.*

The importance now attributed to the study of immunology is shown by the fact that the sixth floor is devoted to the department bearing that name. Its needs have been met by the provision of a laboratory for general class work, quarters for special and advanced students, private laboratories for members of the staff, a centrally placed preparation unit, and quarters for rather a large number of laboratory animals,

because the nature of the class work necessitates the use of a number of animals by each student.

At the London school bacteriology and immunology form one division. It is well housed, but cannot be given such a large amount of space as is available for the two departments in Baltimore. In London it would not be possible for each student to carry out the immunization work with animals which is found so useful in the training at Baltimore.

#### *Physiological Hygiene.*

On the seventh floor is the important department where is studied the application of physiology both to personal and public hygiene. In addition to research and general laboratories and a dark-room for photometric and visual experiments, there is a lecture room accommodating seventy-five students so planned that it can be utilized for experimental and demonstrational exercises in two special directions. Lighting fixtures permit a study of the relative efficiencies of different methods of illumination, while communication by appropriate inlets and outlets with an elaborate air-conditioning plant in an adjoining room enables observations to be made upon the classes of different combinations of temperature, humidity, and movement in the air supplied to the lecture room. This is certainly a novel and presumably also an effective method of impressing upon the students the lessons it is desired to inculcate. The air-conditioning plant is also connected with a special cork-lined experimental room fitted with double windows, a refrigerator door, and ventilating fans. Here the physiological effects of change in atmospheric conditions upon man and animals can be studied. Each member of the staff is provided with an office and a private laboratory, and other rooms are equipped for research work by advanced students. The large laboratory for class work accommodates fifty students.

In the case of the London school it was originally intended to give physiological hygiene a floor to itself, but considerations of cost rendered this impossible, and it now occupies a large part of the first floor. Its general laboratory in size and position compares not unfavourably with that in Baltimore, and, speaking generally, it presents many of the same features. The x-ray section and air-conditioning room had to be placed in the basement, and it is at least doubtful whether the London school can afford to install an air-conditioning plant of the type in use at Baltimore. The question of lighting fixtures for comparing different schemes of illumination has not been considered in connexion with the plans for the London school, and it is doubtful whether the cost would be justified.

#### *Chemical Hygiene.*

In the department of chemical hygiene, which is on the eighth floor, five courses are given:

1. Analysis of food and water, the detection of adulterants, and the exercise of Government control over food products.
2. Analysis of blood, urine, and tissues, designed to familiarize students with methods used in the study of metabolism.
3. Metabolism and diet, covering the more important researches in the field of nutrition.
4. Technique of animal experimentation, designed to meet a demand for workers equipped to enter the field of research in nutrition.
5. Sanitary production and handling of food. During the course industrial plants are visited.

The department has a large student laboratory and fifteen rooms, four equipped as private offices, ten for chemical work, and one for histological study. Eight of these are private laboratories, and each has a shower bath as an emergency in case any student sets his or her clothing alight. One has already rendered timely service in such a case. On this floor also are provided a polariscope and a photographic and a constant temperature room. At the London school the division of chemistry with the department of biochemistry will occupy part of the second floor, which it shares with the division of bacteriology and immunology. It is not so large as the department at Baltimore, but resembles the latter in having a large animal room set apart for biochemical work.

#### *Filterable Viruses.*

A small floor up in the roof houses the department of filterable viruses, which is at present part of the department of medical zoology, but will doubtless before long become an independent unit. The study and laboratory of the head of the department are on the fourth floor, but on the ninth there are two research rooms, a room serving as a secretarial office both for the department and for the *American Journal of Hygiene*, which is here edited, and a room for animals. There are also facilities for photographic work.

It will be seen that this great building has been very carefully designed. It is well built, attractive in its layout, pleasant as a working place, and admirably adapted to the purposes which it has to serve. The Johns Hopkins University is to be heartily congratulated on this accession to its research and teaching resources, and all interested in public health development in the United States and elsewhere will wish the School of Hygiene and Public Health at Baltimore a continuance and enhancement of the success it has already achieved.

## RACIAL DECADENCE.

DAVID LLOYD ROBERTS LECTURE BY THE DEAN OF  
ST. PAUL'S.

BEFORE the Royal College of Physicians on November 19th, Sir JOHN ROSE BRADFORD presiding, the Very Rev. W. R. INGE, D.D., Dean of St. Paul's, delivered the David Lloyd Roberts Lecture, taking for his subject racial degeneration.

Dean Inge began by remarking that eugenics was a branch of science in which he had been keenly interested for many years, ever since he was a near neighbour of Sir Francis Galton in Rutland Gate, and learned from that fine old man to feel some of his own enthusiasm about the possible improvement of the human stock. For him (the Dean) it had been, of course, a hobby rather than a rigorous study, and he could not suppose that any utterance of his on this abstruse and difficult subject would have any value as a contribution to knowledge. It would deal rather with the borderland between strict science and practical social hygiene. Politics ought to be a branch of social hygiene, though at present social hygiene was hardly even a branch of politics; but the subject of racial decadence was one of supreme public interest, and he wished he were better equipped with technical knowledge to state the problem.

He had taken the negative side of eugenics rather than the positive—racial degeneration rather than racial improvement—not because he had any natural tendency to dwell on the dark side of the changes which were proceeding in the human race, but because at present negative eugenics was far more important than positive. Natural selection in a humane and highly specialized country like our own had almost ceased to operate, and if some rational substitute were not provided for it, Nature would punish us for interfering with her methods of social hygiene without providing anything to take their place.

### *The Effects of Specialization.*

All science was based on the belief that in natural laws there was neither variableness nor shadow of turning. Biological progress meant increasing complexity of structure and function, increasing specialization and co-operation of parts, but what was called human progress was more than this. Specialization always meant limitation in some direction (fortunately there were physiological limits to specialization itself); we could not, for example, have both wings and arms until we became angels, and if our limbs were good for running we could not swim like a fish. Highly differentiated organisms were fit only for certain conditions, and when those conditions were changed the organism must either perish or return to a less differentiated type. It was only the least differentiated organisms like the germ cells which were potentially immortal.

In the human species there had been three stages of evolution: increasing complexity of bodily structure, increasing intelligence, and increasing social organization. It was broadly true that when a new stage began the evolution of the earlier stage became less active. To judge from other living organisms on the earth, stability seemed to be the rule, change the exception. It was probable that the four ice ages, divided by long interglacial periods, had had a great deal to do with the evolution of humanity. Perhaps Nature had expended nearly all her ingenuity. There had been no new classes since the appearance of mammals and birds in very early times. Even social evolution seemed to have come to an end. State socialism could no further go than towards a "Socialist Utopia governed and run by maiden aunts." Man had been a distinct

species for probably more than a million years, but anything like specialization was a matter of the last ten thousand years or so, and this was a very short time for him to adapt himself to revolutionary changes in his habits. It was not to be wondered at that disharmony, bodily as well as mental, existed to plague us in our health and conduct. He supposed pathology was mainly concerned with such disharmonies, and it was instructive to notice how small a part disease played in the lives of wild animals, which were better adjusted to their environment.

### *Degenerative Changes in Human Structure.*

It was sometimes said that evolution was rapid to start with, when some climatic or other change set it going, and then it came to a stop; but it seemed possible that physical changes were going on in our bodily structure as rapidly as ever, though, unfortunately, they seemed to be degenerative. It had been pointed out that the foot was altering, the little toe decreasing and the big toe increasing in size, the teeth were decreasing in size and strength, baldness in middle life was perhaps increasing, and something seemed to be happening to that apparently useless organ the appendix. He could not help thinking that eyesight had deteriorated rapidly. Very few middle-aged men could read a closely written or printed mediaeval book without glasses, though the ancient Greeks went on reading and writing without mechanical assistance till extreme old age. Nearly all the aptitudes which distinguished the handy man from the simpleton were now becoming superfluous. We might some day have a generation which could neither walk nor write, relying on the car in the one case and the typewriter in the other. Nature would leave us just enough intelligence to "press the button."

Had human intelligence advanced during the last five thousand years? It seemed very doubtful. Look at the ancient Egyptians living in large and well ordered communities, with all the facilities of a complex civilization. He would not go so far as Sir Francis Galton in estimating the comparative intelligence of the ancient Athenians, but there could be little doubt that the Greek was our superior. Civilization was mainly the result of accumulated knowledge and experience; each generation stood on the shoulders of the last, and had the chance of climbing higher from that point. Most of our acquisitions were in the custody of very few persons. Some of them were trade secrets, others could be mastered only by long years of application, and this explained why the arts and structure of civilization had occasionally disappeared. Some calamity might break the tradition. In medicine Celsus and Galen were far in advance of the superstitious and ignorant practice of the Middle Ages. It was unlikely, but not inconceivable, that such a disaster might occur again. There was a contemporary example in Russia, which, when it recovered, would have to go to Germany and other countries for the arts and sciences which had been almost extinguished at home.

### *An Industrialized Civilization.*

Analogy suggested that where the weight of sustaining civilization was thrown upon tradition other faculties by which man slowly raised himself from savagery were likely to become partially atrophied. Whether such atrophy could be inherited was a vexed question into which he, an outsider, would be wise not to enter. It could not be disputed that those qualities which were once essential to progress had no longer the same survival value under civilization of the modern type. An industrialized civilization skimmed off the cream in each generation and then threw much of it away. In some societies a highly cultivated minority had flourished and produced achievements which were the wonder of posterity, but the remainder of the population were still quite uncivilized and uncared for. There had been biologists who accepted this type of State as the best. Benjamin Kidd also thought that cut-throat competition resulted from deep-seated physiological causes, the operation of which was inescapable. But unlimited competition exhausted the competitors, and, whether voluntarily or involuntarily, sterilized them. So severe was competition in the United States that 1,750,000 policy-holders of insurance companies gave an average life of 46 years for males and 52 for females. But in all the higher faculties

competition was not the chief motive force. The millionaire was not the supreme human product.

Altogether the lecturer did not think that those who wished to keep the masses in a servile state—if there were any such left—could appeal successfully to biology in support of their views. A society with well marked castes might be successful, partly because by encouraging good traditions of skill in element of specialization it but not if it included an ignorant and wretched proletariat. The plan of developing to the utmost a small selected class had been tried several times, but it had not been proved that equally good results might not have been obtained by other methods involving less injustice.

#### *The Relative Importance of Nature and Nurture.*

It had now to be considered (Dean Inge continued) whether civilization was working towards the degeneration of the national stock. It was necessary to take into account, not only the parasitism of persons or classes on the community, but the new danger that human beings might become parasitic to the machines which they had made for their own use. This last was obviously a problem which belonged to the human race alone. It would be generally admitted that social science had been too exclusively environmental, though it was not necessary to minimize what could be done by external means, such as education, sanitation, and increased opportunities for leading a healthy life. Sometimes the diseases which were supposed to be hereditary could be eliminated by scientific treatment, instancing the freeing, almost, of the Swiss valleys from goitre, which had been endemic there ever since the time of Juvenal. It used to be supposed, again, that Europeans were constitutionally unable to keep their health in a tropical climate, but it seemed now that in the absence of tropical diseases, such as malaria and yellow fever, which were being brought under control, even northern Europeans could live healthily in climates as hot as that of North Queensland. Still, when all had been said in favour of concentrating attention on the environment, the best authorities were unanimous that nature was far more important than nurture. Professor Karl Pearson had come to the conclusion that if the relative importance of nature and nurture in determining bodily and mental character were compared it would be found that nature was at least five times—perhaps even ten times—more decisive than nurture.

#### *Hereditary Transmission of Characters.*

Transmission of characters was now seen to be far more complex than was once supposed. Much might still be learned by collecting families and observing what qualities tended to reappear in the second and succeeding generations. Galton hardly allowed sufficiently for the good stock which the son of an able man possessed—the stimulating influence of the home circle in which he was brought up, the ambition to follow in his father's footsteps, the opportunities of good education which his father's success enabled him to procure, and, in some professions, such as politics, the opening which he secured into the profession by virtue of his father's prominence in it. It would also be found, if the literature of the subject were studied, how frequently striking pedigrees, such as the Bachs, the musicians, and in our own country the Darwins, made their appearance. A much larger number of pedigrees was needed, including not only five-talent but two-talent men. Inheritance of high stature and other physical qualities could not have escaped notice, and if matings were made with a view to preserving some particular character there was no reason why that character should not be secured. The qualities which led to distinction in humane letters appeared to be strongly inherited; the inheritance of skill in mathematics appeared to be more sporadic. The history of many professional families would be well worth tracing in detail.

The lecturer went on from this to speak of the falling birth rate among the professional classes. The higher races and classes were using the resources of scientific knowledge to reduce the death rate of the inferior and the birth rate of the superior. If *Who's Who* were opened at random and

the number of children in fifty or a hundred consecutive entries were counted the average would be found to be slightly less than two for each entry, so that these families of moderately successful men were not keeping up their numbers. This relative sterility of the professional classes was a new thing; so was the sharp decline in the infant mortality of the slums; so was the feminist movement, which, according to some, was the most dangerous factor of all because it made the most intellectual women decline marriage or motherhood. Beyond all question the classes best endowed intellectually, and, in this country, the best endowed physically as well, were passing into a relative or even an absolute decline. Taking the country as a whole, the lowest birth rates were in the families of members of the medical profession, teachers, and ministers of religion; yet no more desirable parents could be found than the members of those professions. Before leaving the subject of good heredity, he called attention to one of the most remarkable examples of how a country might be permanently enriched by a very small accession of racial stock. To judge from the claims of some prosperous Americans, it might be supposed that the *Mayflower* was as large as the *Olympic*! But in fact only thirty-three pilgrim fathers founded families. The names of some of the most distinguished of their descendants included many Presidents of the United States, and other distinguished men in American politics, arts, and letters. Nearly half the distinguished men in America were descended from those thirty-three pilgrim fathers.

#### *The Propagation of Bad Stocks.*

Finally the Dean turned to the injury done to the national stock by the unchecked propagation of bad stocks. The feeble-minded were about 50 per cent. more prolific than the normal. The researches of Tredgold were decisive on that point. It was not generally known that although the death rate had declined rapidly, this decline had been entirely in the earlier periods of life. The expectation of life at 60 was no higher than it was two generations ago. From the age of 45 cancer began to levy a cruel toll on both sexes. Was the national physique improving or deteriorating? On the Continent it had been found that the stature of Danes had risen appreciably during the last fifty years. The average height of the Dutch had risen during the last third of a century. In France the average height of women was said to have increased by 3 cm. during the last eighty years. There were no figures, apparently, available for England, but recently in the *English Review* certain statements were made suggesting that there had been a marked deterioration among the people of this country. It would be interesting to know whether those statements could be challenged. The matter was serious, especially if, among Continental peoples, the tendency was the other way.

There was another means, besides dysgenic selection, by which the stock might be impaired. Modern workers were parasitic to the machine which had ousted them from natural human occupation. Apart from the machine they would be helpless, even in the presence of abundant material. A company of such men, left to themselves without their machines, would most likely perish.

Nevertheless, he was inclined to hope that it was not too late to stop the mischief, which had not yet had time to go very far. We must hope for the generation of some social antitoxins. We were not yet a degenerate people. We were a race to which any man might be proud to belong. But society was not at present in a healthy condition, and unless the problem of racial decay were taken in hand it might be too late. All they could do at present was to persuade their countrymen what were the pressing problems—so very different from those in which politicians interested themselves. The great medical societies could do much if they would speak out. They did not realize how eager the public would be to listen to them. The modern man might deny that he had a soul, and forget that he had a mind, but he was acutely conscious that he had a body, and accordingly he had a great respect for the doctor. Personally the Dean wished that the medical societies would testify, for when they spoke he nearly always agreed with them.

# British Medical Journal.

SATURDAY, NOVEMBER 27TH, 1926.

## THE UNIVERSITY OF LONDON: A NEW PHASE.

DURING the past few weeks two incidents of great importance have occurred in connexion with the University of London. It will be remembered that in 1920 the Government purchased a site of eleven acres to the north of the British Museum, and offered it to the University on certain conditions. One of these conditions postulated the removal of King's College to a portion of the site. After prolonged negotiations between the University, the Treasury, and King's College, King's College determined, at the end of 1925, not to remove itself to the Bloomsbury site. Under these conditions it was impossible for the University to accept the site on the terms on which it had been offered. Although communications were made to the Government with the object of having the site conveyed to the University so that it might be utilized for various University purposes, the Government, in view of the inability of the University to accept the site on the conditions under which it was offered, invited the Duke of Bedford, in accordance with the terms of the original sale, to take it back at the price at which it had been purchased—namely, £425,000. The Duke of Bedford accepted this offer for repurchase, and consequently for the time being the site, as a whole, was lost to the University.

Recently, however, the Chancellor of the Exchequer indicated that he would be prepared to give a certain capital sum to the University, part of which should be used for the purchase of a portion, or as much as possible, of the Bloomsbury site. The Senate, at its meeting on October 20th, decided to enter upon negotiations with the Bedford Estate for the purchase of the blocks of land on either side of the British Museum Avenue between Keppel Street and Montague Place. These negotiations are now proceeding, and, we trust, will come to a successful termination.

The exact University purposes for which this land will be utilized have not yet been settled. The main principle, however, decided by the Senate is that the central administrative offices should remain at South Kensington in the buildings known as the Imperial Institute. The University institutions which it is considered possible may be placed on the land which is acquired at Bloomsbury are the Institute of Historical Research, the School of Oriental Studies, the Architectural Atelier, the Students' Union, the General University Library, the headquarters of the University contingent of the Officers' Training Corps, and so on. It will not be forgotten that on a site immediately adjacent to that indicated above the building of the London School of Hygiene and Tropical Medicine is being erected. We have also heard it suggested that if arrangements can be made Birkbeck College is very desirous of acquiring a portion of the Bloomsbury site. As is well known, the buildings and accommodation of Birkbeck College are extremely cramped, and from their position cannot be readily enlarged so as to meet present requirements.

If the negotiations of the University are successful, and it acquires those portions of the Bloomsbury site

which it desires, there is no doubt that an important movement towards the establishment of a University centre in London will have been brought about.

The second point of importance is the fact that the University of London Bill passed its second reading in the House of Commons on November 19th, and that the money resolution required for the bill was agreed to in Committee. The bill, which has already passed through the House of Lords, was introduced in the Commons by the President of the Board of Education, Lord Eustace Percy. He stated that the object of the bill was to appoint statutory commissioners to draw up statutes for the University of London in general accordance with the report of the Departmental Committee, issued in March, 1926. He said that the bill, in the main, followed the lines of the measures which had already been introduced for the Universities of Oxford and Cambridge. If reference is made to our analysis of the report of the Departmental Committee in the JOURNAL of May 22nd, 1926 (p. 875), it will be seen that the chief recommendations of that committee consisted of two things. First, to modify the present constitution of the Senate so as to give representation on it to the constituent schools of the University. At the present time the only constituent schools which have direct representation on the Senate are King's College and University College. Secondly, the departmental committee proposed the establishment of a Finance Council to deal with all questions of finance. It is not recommended in the bill that the Commissioners should alter the representation of the faculties or the body of graduates on the Senate. It does, however, entail a reduction by the removal from the Senate of certain nominated members, such as those who in the past have been appointed by the Royal College of Physicians, the Royal College of Surgeons, the Incorporated Law Society, and the Inns of Court. The reason the Departmental Committee gave for the elimination of these nominated senators was that they could not get any proper organic representation of the schools of the University without eliminating some of the present members. Lord Eustace Percy stated that it was not proposed to interfere with the rights of either theological colleges or external students. Dr. Little, in moving the rejection of the bill, based himself on the lines of the now defunct Haldane report. The arguments he used, however, were mainly in favour of reform coming from within, and of ensuring that there should be no interference with the supreme authority of the Senate in all matters financial and academic. These arguments, however, did not convince the House of Commons, and the bill was read a second time without a division.

Most of those who have had experience of the detailed working of the University, especially as regards its administration, entertain no doubt that the establishment of a new Finance Council and the modification of the constitution of the Senate on the lines proposed will tend in the future to great improvements in all branches of University work in London.

As regards the work of the Finance Council, it is proposed that the Government grant of about £360,000 (at present given through and allocated by the Universities Grants Committee) and the grant from the London County Council of £70,000 shall be paid to the University as block grants, and it will be the duty of the Finance Council, after receiving recommendations from the institutions concerned, either direct or through the Academic Council and the Senate, to allocate this grant. The creation of a Finance Council

on the lines proposed will enable men of great experience in finance and public and municipal work to take an active part in the promotion and advancement of University matters in London. In the past, owing to the constitution of the Senate and the method of administration such a constitution entailed, it has not been possible to any great extent to appoint men to the Senate who had such experience.

### HOSPITALS AND ROAD ACCIDENTS.

It is of some interest to recall the forebodings of disaster and danger that heralded the coming of the railway train, and to note how amazingly safe the railroad has proved. The motor car did not arouse similar fears at its coming—merely popular curiosity. The red-flag-to-the-fore of its early days was a relic of the fear of the locomotive. The automobile has increased local mobility in astonishing fashion. No one thinks anything of a fifty-mile run; it will be done on the spur of the moment, with no more preparation than securing a can of petrol. But it has brought more problems than did the revolutionary railroad, for the car has penetrated our common life, and not been built up alongside it like the railway. Local mobility has increased to such an extent that it has almost choked itself. Hence the problem of the city streets, and of by-passes and of parking. Road accidents on the highways, at crossings and bends, are in a different category. Here the primary cause of accident is speed. When cars were unreliable machines half of the driver's consciousness was absorbed in listening to the sounds of his car; such speed as his car could accomplish he dared not attempt, because of that dubious sound which might threaten a breakdown. Now smooth, almost inaudible, swiftness is the common measure of the least of cars. Fifty miles an hour can be touched on a fair road, and the high average of thirty miles an hour for long journeys is within the compass of a car costing a hundred and fifty pounds. The ease of speed makes speed easy. Driving becomes monotonous; slackness and rashness are engendered. At the moment of stress the driver is at fault. He is too late in slackening speed, too eager to seize an advantage, too sudden with his brakes, and there is a crash. The consequences are recorded daily in the press.

The frequency of these road accidents is causing a serious disturbance of hospital bed accommodation. Beds that were intended and are needed for the sick poor are occupied by the victims of motor cars. We hear of hospital wards where there is no room for appendix cases because all the beds are occupied with accident cases. Again, the finances of the hospitals are disturbed. Funds that were given by benefactors for the sick poor are diverted to the relief of those well able to pay for their treatment or for whom insurance should provide. The doors of the hospitals are rightly ever open to the call of the injured, whether he has fallen amongst thieves or been mangled by a car. But, unlike the good Samaritan, who paid his two pence to the innkeeper for the care of the injured stranger, those concerned with the victims of motor smashes too rarely remember the cost to the hospital, and the skill and care of the hospital doctor. Mr. Bishop Harman, in his paper on "The modern hospital conception," read at Windsor (p. 984), calls this exploitation of the hospitals and their staffs "modern hospital abuse," and roundly charges the wealthy insurance companies and their shareholders with exploiting charity for the business of earning

dividends. Part of the blame for this lies with the hospital boards and medical staffs; they have not readily asserted their just claims. But there are signs of an awakening. In recent issues of the JOURNAL we have quoted reports of action or projected action by hospital boards coming from widely separate parts of the country, the latest from Edinburgh and Aberdeen. New accident wards are being provided, and the cost of these and their upkeep should be met by the recipients of the treatment or by those who act on their behalf. We hear of one such ward to be opened shortly at the West London Hospital, where the munificent donor of the ward and its equipment stated that he was prepared to meet the deficit on the upkeep of the ward provided the patients paid such share as they were able. That stipulation is a sign of the times.

The subject of the attitude hospital authorities should take up with regard to cases of accident admitted to their wards when the injured person is insured was considered by the Annual Representative Meeting of the British Medical Association in 1925, and again this year. The opinion was unanimous that in all such cases where medical attendance is covered either directly or indirectly by insurance, the hospital authorities should recover from the insurance company the full cost of maintenance and treatment of such patient. The Representative Body also recorded its opinion that where patients who would ordinarily be considered as private patients are admitted to hospital solely on account of accident or emergency, they should be considered "private patients." Members of the staffs of hospitals will no doubt be glad to quote this expression of opinion by the Representative Body to reinforce advice they may themselves think it proper to give to the boards of their hospitals.<sup>1</sup> It is to be anticipated that the members of such boards will appreciate the equity of the suggestion, and the directors of the Aberdeen Royal Infirmary have already resolved to ask insurance companies to accept responsibility, while at Edinburgh the matter is to be raised again at the beginning of next year, when a return of the number of cases admitted to the Royal Infirmary owing to motor accidents will be available.

### ANALOGIES AND CRITICISMS.

AFTER-DINNER speaking is a difficult art, and unless it reaches the high level attained at the annual dinner of the Royal Society of Medicine last week listeners are apt to be disappointed. At a medical dinner it is customary for a speaker not belonging to the medical profession to seek for some ground of analogy or comparison between it and his own. We have all appreciated the generous attempts of clerical speakers to recognize an alliance or similarity of purpose between Medicine and the Churches, and some of us think we have detected an increasing disposition to answer the question, Who shall minister to a mind diseased? by saying, "Both of us working together." Evidence is increasing that the wiser among the clergy are learning one of the lessons which medicine has to teach—namely, that really bad people are very few, and that much of the irritability that spoils domestic life and leads to deeds of cruelty and violence is due to physical causes which medicine can alleviate or

<sup>1</sup> The resolution was approved at the Annual Representative Meeting in 1925. At the meeting this year it was formally adopted and became the policy of the Association. The full text will be found in the SUPPLEMENT of July 24th, p. 55.

remove. The lawyer finds it a little more difficult to draw a parallel, for he—the barrister at any rate—sees for the most part the seamy side—the evil passions, the obstinacy, the falsehood, and the cunning, by which the good in human nature is so commonly perverted when it gets into the law courts. Though we may agree that the Bar has been and is one of the chief bulwarks of our liberties, the change in mentality which comes over the better sort of advocate when he reaches the Bench is one of the curiosities of psychology. Some other professions—the chemical and engineering, for example, which have to do with bodies possessing properties which can be exactly measured and controlled, and their actions and reactions foreseen—do not venture on a comparison, and all that Sir William Bragg, speaking at the dinner as a physicist and chemist, could claim was that chemistry and physics were able to help medicine in many ways, and thus in part to repay the debt general science owed to the physician at the time of the great renaissance of science which marked the close of the seventeenth and the opening of the eighteenth century.

The Prime Minister had an easier task when he compared medicine with his own profession of politics. Both are attended by the uncertainties and surprises inseparable from the idiosyncrasies of man, the variations between individuals and in the same individual at different times. *Varium et mutabile*, though said of woman, is true also of the other sex. It is one of the conditions the politician must accept, as it has to be accepted also by medicine—with this difference, that the patient is perhaps on the whole more loyal to his doctor than the voter to his party leader. Possibly that is because, as Mr. Baldwin admitted, legislation so seldom produces immediately the result desired. Sometimes the law courts decide that Parliament has not said what it meant; sometimes the results sought, though they are attained in the end, are long in coming, and the voter, growing impatient, seeks another opinion and installs new rulers; sometimes changes at home or abroad alter entirely the nature of the problem to be solved. Perhaps Mr. Baldwin made his best point when he likened the community to the living body, for his description of the State might be applied without alteration to the living body—an infinitely complex assembly of growing structures, the cells that compose it being always born and always dying, while throughout the change a moving equilibrium of the whole is maintained. Sir Berkeley Moynihan worked out another happy example of an analogy, suggested by Dr. Robert Hutchison, and ingeniously sustained it in light and humorous vein.

Sir James Berry's speech from the chair afforded an instance of a quite other sort of purpose an after-dinner speech may be made to serve: it may be used, as he used it, to raise on an informal occasion a matter of serious import. His point was that one after-effect of the war had been the spreading over this and other countries of a wave of enthusiasm for operative surgery. When he said that major operative surgery should rest on a solid foundation of pathological anatomy, and that war surgery, mainly the surgery of injuries in healthy men, was not in itself alone a complete school for the surgery of civilian practice, he no doubt only expressed an opinion to which the majority of the profession would subscribe. His further statement that many difficult and dangerous operations are being undertaken by those whose training, experience, and judgement are often insufficient was, we readily believe, made from a stern sense of duty and with reluctance. It needed, as Sir Berkeley Moynihan afterwards observed, some courage

to say such a thing. Of the extent to which it is justified we have no means of forming any reliable judgement. That it will cause some resentment our correspondence columns already afford evidence. If it gives rise to a temperate and reasoned discussion within the medical profession it will probably have done good, but it has already been seized upon by some of the less responsible newspapers. This is unfortunate, though no doubt inevitable.

#### ACUTE POLIOMYELITIS.

THERE seems, we are glad to say, to be some reason to believe that the crest of the wave of the epidemic of acute poliomyelitis has passed, for we understand that the notifications, which reached a total of 319 in October, numbered only 65 in the two weeks ending November 13th. If this happens it will be in accordance with previous experience, as the disease in this country has usually reached its greatest prevalence in the summer and declined at the beginning of the winter. The statistics of the incidence of acute poliomyelitis and polio-encephalitis given to the House of Commons by the Minister of Health on November 23rd (p. 1026) indicate that though the disease in other countries as well as in this did not disappear during the first half of 1925, its incidence was much lower than in the second half of that year. In England and Wales the contrast is of 132 to 290. In the Scandinavian countries, including Finland, the number of cases notified in the first six months of 1925 was 136; in the second six months of 1925 it was 578. The figures for Norway apply to the towns only. The number of cases in England and Wales in the first six months of this year was 136; since the beginning of July the number of cases notified of acute poliomyelitis (alone) has been 738. That we must not assume we are yet out of the wood is shown by the facts mentioned in another column this week (p. 1019) by Dr. J. E. O'Connor for the Leicestershire and Rutland Combined Districts, and by Dr. Clapperton as to Oakham. The first two cases occurred in Oakham during the week ending October 9th, and there were two cases—one each in the urban and in the rural district—as late as November 6th. The outbreak at Grays Thurrock, so carefully studied by Dr. Boul, medical officer of health, occurred at the usual season. It will be seen from the abstract of his report, published at page 1007, that the chief prevalence was in July and August; the number fell from 31 in August to 6 in September, and there has been, we gather, no case since. The details of the Grays epidemic, so fully obtained by Dr. Boul, afford strong evidence that the disease is communicated either directly by association between one person and another, or; as other observations have made pretty certain, by carriers. Dr. Boul was able to discover 58 cases, and of these 11 died; this is a death rate of approximately 19 per cent., and therefore rather less than that observed in the great epidemic in New York in 1916, when it was 25 per cent., but higher than that of 10 to 12 per cent. commonly assigned. This, however, is only part of the toll taken by the disease, for 28 of the persons attacked at Grays are left with a greater or lesser amount of paralysis. The position with regard to Uppingham School appears to be satisfactory; since the school was disbanded only one case has occurred, in a boy who was attacked in his own home. It will be remembered that, owing to the occurrence of two cases of poliomyelitis, the school was closed on November 13th, and the boys sent home by the authorities for sixteen days, and told to return on November 29th. The wisdom of this decision was challenged by Lord Dawson of Penn and Dr. James Collier in a letter published in the *Times* of November 16th. On November 18th the school

authorities for the first time consulted Sir Humphry Rolleston, and as a result the above decision was reconsidered. The parents were informed that, as it was impossible to give an assurance that no further cases would occur when the school reassembled on November 29th, it had been decided that the boys should not return to school this term. The advice not to reopen before Christmas was based on several considerations, such as the desirability of allowing for a fully ample period of incubation and accompanying quarantine; the short duration of the remaining term (just over three weeks from November 29th); and the possible untoward influences of travelling in winter on the boys' resistance, and of a return to the environment where two cases had already occurred. We feel that we are absolved from now discussing further the policy of disbanding Uppingham School by the letters which, in response to our requests, we have received from Dr. Miller and Dr. Dunn; they are published at page 1019.

#### MERCUROCHROME.

DURING the last decade an intensive search has been pursued for some drug which will act as an internal disinfectant in cases where bacteria have established themselves in the body. Numerous new drugs have been prepared by organic chemists, but in most cases the clinical results have been disappointing. In the case of the dye mercurochrome-220 there is, however, a very considerable quantity of favourable clinical evidence, which has come from several different countries. Mercurochrome-220, or di-brom-oxymercuri-fluorescein, was introduced in 1919 by Young, White, and Swartz. The number attached to the name indicates its place in a series of disinfectants examined by these workers at the Brady Urological Institute, Baltimore. The drug has been found to be a general disinfectant of high value, and when applied in 2 per cent. solution to open wounds or mucous membranes it exerts a powerful and prolonged disinfectant action and produces little local irritation. The action of the dye as an internal disinfectant has, however, attracted especial attention; it is given intravenously in 1 per cent. solution in doses up to 5 mg. per kilo body weight. The drug has been tried in a large number of different types of infection, and some very remarkable results have been recorded. In a recent communication Young<sup>1</sup> gives records of 680 cases treated with mercurochrome-220. His records show that in 173 cases of septicaemia a cure was effected in 63 per cent. Successful results are also recorded in leprosy, anthrax, and malaria. In acute encephalitis his records show that five cases were treated and that all were cured or improved, but that in residual cases no improvement occurred. The drug was used by Dr. Dunn in the second case of polio-encephalitis at Uppingham School. A single intravenous injection, given within a few hours of the onset of symptoms, was followed by an immediate improvement, and on the fourth day the boy was convalescent. Young did not find much benefit to follow the use of mercurochrome in ten cases of meningitis. Others have given rather less favourable reports than Young of its action in various diseases, but most observers are agreed that the drug often produces remarkable benefit, even in severe cases of generalized infection. The clinical reports are supported by extensive laboratory experiments. Young, for example, tested the drug in pneumococcus septicaemia in rabbits and in anthrax in guinea-pigs, and found that practically all the untreated controls died, but that mercurochrome injections saved about 50 per cent. of the animals. The drug is, of course, a powerful agent, and therefore can produce undesirable side-actions. The most unpleasant side-action is a painful colitis due to the

action of mercury on the gut. Some workers also have accused the drug of producing kidney injury—an effect that is likely to follow the intravenous injection of any organic mercurial drug if given in large doses. Young denies, however, that this is a serious danger if proper care is exercised. Time is of course needed in order to arrive at a final estimate of the value of any new drug, but the evidence existing regarding mercurochrome-220 is sufficient to entitle the drug to the careful consideration of the medical profession in this country.

#### ERRORS IN DIAGNOSIS.

If there is one thing the doctor would like to repress into his "unconscious mind" it is the remembrance of his errors in diagnosis and treatment. The repression, however, might cause some dreadful complex of depression; so that perhaps it would be better if the peccant practitioner sought help against future blunders by reading Sir David Drummond's article in the October issue of the *Newcastle Medical Journal*, now edited by Dr. F. J. Natrass, on "Our mistakes and how they are made." We all make mistakes, Sir David Drummond says truly; whether everyone acknowledges all his mistakes is, perhaps, debatable. Unfortunately, we must agree with him that most of our mistakes in diagnosis are avoidable; and that the commonest explanation of a diagnostic error is carelessness. To plead, as an excuse for carelessness, overwork or lack of time is, says the author, no vindication, since no man is justified in undertaking more than he can perform. This, however, is a hard saying, because some doctors have more work thrust upon them than they would wish to undertake. Sometimes trouble in diagnosis arises because the doctor is looking for a complete clinical picture, and fails to recognize a case in which some usual symptom of the disease happens to be absent. In other cases a careful history of the patient has not been taken; or all the possibilities in a difficult and doubtful case have not been reviewed. Many of our profession, it is said, have fallen into a bad habit of postponing the investigation of a new case until a more favourable season, with the result that a mental impression of the condition, based upon nothing substantial, is accepted as diagnosis. Sir David Drummond objects to the "snapshot" diagnoses of the man who relies on his clinical instinct; and he calls attention to two curious psychological sources of error—the tendency in some men to seek an unusual diagnosis while overlooking the commonest cause, and the habit of others of allowing the mind to be influenced unduly by the findings in a previous case. Several of these causes of error are illustrated by cases which have been met with by Sir David Drummond during his practice as a consultant; but he has not gratified our curiosity by confessions drawn from his own soul.

#### PUBLIC HEALTH IN THE INDUSTRIAL REVOLUTION.

POLITICAL economists do not as a rule interest themselves to any great extent in medical science, but Mr. Buer, the lecturer on economics in the University of Reading, must be regarded as an exception. He has written an essay<sup>1</sup> on health, wealth, and population in the early days of the industrial revolution, which deals almost entirely with vital statistics, town improvements, water supplies and drainage, British pioneers in public health, hospitals and dispensaries, general hygiene, and midwifery during the period 1750 to 1815. He discusses also rickets, scurvy, antiseptics, leprosy, plague, small-pox, typhus, fever hospitals, and malaria.

<sup>1</sup> *Health, Wealth, and Population in the Early Days of the Industrial Revolution.* By M. C. Buer, B.Sc.(Econ.). London: Routledge and Sons, Ltd. 1926. (Demy 8vo, pp. xi + 290. 10s. 6d. net.)

<sup>1</sup> *Journ. Amer. Med. Assoc.*, 1926, 87, 1926.

He advances reasons for rejecting the common view that the great increase of population, during the years when industry began to feel the influence of the discovery of the steam engine, and with it the development of factories and machinery, was due to an increase in the birth rate consequent on the promiscuous herding of families in industrial towns; he attributes it to an astonishing decrease in the death rate, consequent on town improvements and on a raising of the standard of social hygiene and public health. He points to the increased wealth of London, where the commerce and foreign trade of the country were concentrated. Ship-building and other industries developed rapidly; and the demand for agricultural products to feed the growing population of London and of the industrial cities stimulated agricultural improvements, and led to increased facilities for transport by land and water. Food became cheaper and abundant; and sugar and tea were added to the national food supplies from our oversea possessions. With these the "grim spectres of famine and pestilence, which were never far distant" in previous years, were laid. Better building materials were brought to the towns owing to better transport facilities and the increase of capital; streets were widened and paved, drains were covered in, water supplies were improved, and easily washable cotton took the place of woollen clothing, leading to greater personal cleanliness, while iron bedsteads in place of the old wooden constructions diminished vermin. To the wealth of London is also attributed developments in medicine and in social philanthropy, such, for instance, as the great hospital movement of the eighteenth century. All of these factors had, Mr. Buer considers, an astonishing effect on the death rate. The sources of information regarding vital statistics of the period are limited, and consist mainly of parish registers, bills of mortality, certain taxation returns, and estimates of population by Rickman and Finlaison, and of the Carlisle tables compiled by Dr. Heysham in 1815. Mr. Buer discusses their value in a lucid manner, and points out certain errors and false deductions which have been made from them. He exemplifies the influence of individuals of force and character in bringing about the changes in public health to which he attributes the rapid fall in the death rate. As Arthur Young, the agriculturist, said at the end of the eighteenth century, "Everything is well done in England except what is done with public money," and he instanced the practical results of individualism as opposed to bureaucracy. In his chapter on the pioneers of public health Mr. Buer enunciates a truth when he states that "war was a great stimulant to advance in medical practice, and that the origin of modern public hygiene must be sought in the departments of naval and military hygiene." The outstanding naval and military figures of the period were Pringle, Lind, and Gilbert Blane—incidentally, Mr. Buer omits Jackson, who was probably greater even than these—while Percival and Ferriar in Manchester and Currie in Liverpool are mentioned as the prime movers in public health reform in civil life and in the organization of civil hospitals and dispensaries in these cities. Mr. Buer's essay is a valuable addition to the history of medicine and social hygiene, more especially as it comes from the pen of one who has studied closely and accurately the social and health conditions of the latter half of the eighteenth and early years of the nineteenth century from a political economist's point of view.

#### AWARDS AND DECORATIONS.

THE Royal Society of Medicine has honoured itself by presenting its gold medal to Dr. J. S. Haldane, F.R.S., of Oxford. It is a suitable recognition of a long life devoted with singular, but hereditary, ability to the study of some of the most fundamental problems of physiology.

There can be no more fundamental problem than that of respiration—its smooth working in health so that we are unconscious that it is going on night and day, and its disturbances by abnormal conditions in the environment. While his outlook on life is that of the philosopher, he has never lost touch with practical medicine, and of this his many contributions to our columns are evidence. His researches have elucidated the physiological conditions of respiration at high elevations as well as those which arise in the vitiated atmosphere of mines. The medal was founded by a gift from the late Dr. Robert Murray Leslie, and previous recipients have been Sir Almoth Wright (in 1920) and Sir F. Gowland Hopkins (in 1923). The society has also received a most welcome gift from Sir StClair Thomson, consisting of a chain to be worn as a decoration by its president on formal occasions. It is of 20/22-ct. gold, and has forty-nine links. It is unquestionably at least 300 years old, being described by the experts who have seen it as "circa 1600." Its authenticity and artistic value have been vouched for by experts at the South Kensington Museum and by well known artists, and Royal Academicians have expressed the opinion that there is no more beautiful chain of office in London. The colour of the gold is very deep, and the patina is of an exquisitely mellow quality. The form of the links is interesting, as each is composed of two delicately pierced concave discs placed rim to rim, the appearance of one link very much resembling a flattened pomander ball. There are two designs of link, one having eight cusps and the other four cusps on its circumference, alternating with radial arms. There is no history obtainable as to the original purpose of this chain. It is doubtless of Italian workmanship, and is such a chain as may frequently be seen in pictures of statesmen and princes of the Cinquecento. The Royal Society of Medicine has decided that its present badge is out of harmony with the chain. This badge is, in fact, that of the Royal Medical and Chirurgical Society, to which it was presented by Sir Edward Sieveking in 1890. The council intends to apply for a grant of arms, the shield of which will no doubt be reproduced in a suitable badge, and has accepted Sir StClair Thomson's offer to defray the expenses connected with this so that the chain and badge may be complete.

#### AMERICAN IMMIGRATION LAWS.

THE effects of United States immigration laws are engaging the attention of American sociologists. Dr. Clifford Kirkpatrick has published a detailed examination of the effects of immigration upon the intelligence of the population as measured by modern psychological tests. He gives an account of the methods of study, the work of previous investigators, and of an extensive investigation of his own, in a work entitled *Intelligence and Immigration*.<sup>1</sup> He concludes that there was at one time a supreme opportunity for developing a population of the highest quality in certain respects by the careful selection of immigrants, but that the opportunity was little appreciated. In general the findings of his study give little credit to the immigration policy of the past. He owns that intelligence is not the only trait of social significance, and that innate traits do not altogether dominate cultural considerations. Italians may have musical ability that goes far to balance deficiencies in other respects. Nevertheless, the findings indicate that there is a serious tendency for groups, apparently of lower intelligence, to be the very groups that in the last two decades have entered the country in the greatest numbers. There are exceptions. Some of the Jewish peoples are possessed of considerable ability. The Finns compare favourably with some Americans. It is

<sup>1</sup> *Intelligence and Immigration*. By Clifford Kirkpatrick, Ph.D. Baltimore: The Williams and Wilkins Company; London: Baillière, Tindall and Cox. 1926. (Med. 8vo, pp. 123; 5 figures, 18s. net.)

thought probable, on the other hand, that the Italians, the Poles, and the Russians have a depressing effect on the average of American intelligence, and that the French Canadians have not raised it. Since much of the evidence is derived from the achievement of school children rather than from the immigrants themselves, even making due allowance for the influence of a language handicap, the findings are such as to raise grave doubts as to the success of the "melting-pot." There is another aspect of the matter which it is considered makes the shortcomings of the past immigration policy more serious—differential birth rates. The data collected appear to show that the higher birth rate is associated with inferior qualities. The author criticizes the "group selection" put into force by the law of 1924; there is, he says, no doubt that tremendous overlapping occurs, and that the best of the Southern Europeans are far superior to the poorest of the Northern. He would have an individual selection of immigrants based on scientific measurement and evaluation made as completely objective as possible, and the selection, he considers, should be made in the Eastern hemisphere. The effects of such a fine-tooth comb may be imagined. So far as it was effective its tendency would be to denude Europe of its best for the benefit of the United States of America. Possibly there would be a revolt on this side against such a policy, and it is conceivable that the States might be made to pay in cash for the value of the immigrants they receive.

#### SOCIETY OF MEDICAL OFFICERS OF HEALTH.

The annual dinner of the Society of Medical Officers of Health was held at the Piccadilly Hotel, London, on November 18th, with the President, Dr. E. H. Snell (M.O.H. for Coventry), in the chair. In proposing the toast of "Prosperity to the Society," Sir Robert Bolam said that he brought a message of goodwill from the British Medical Association. Isolation of the medical officer of health was not in the interest of the common health, and reciprocity of ideas and knowledge between the Society and the Association was most beneficial to all. He coupled the toast with the name of the President, who during twenty-eight years of good work for his city had given much help on committees of the British Medical Association. Dr. Snell, in reply, spoke of the increasing intimacy between the Society and the Association that had grown up during Sir Robert Bolam's term of office, and gave a most entertaining retrospect of the progress of hygiene in the seventy years of the Society's existence. The health of the visitors was proposed in warm phrases by Dr. Charles Sanders, whose text was: "A society is known by the guests it entertains." The toast was responded to by the Duchess of Atholl, M.P., Parliamentary Secretary of the Board of Education, the Right Hon. Philip Snowden, M.P., formerly Chancellor of the Exchequer, and Sir John Rose Bradford, M.D., F.R.S., President of the Royal College of Physicians of London. The Duchess of Atholl expressed the opinion that the greatest development in the past twenty-five years had been the inception and growth of the school medical service. Another gain had been the assistance given to the cause of health by women members of Educational Committees. She ended with a tribute to the work of medical women in school hygiene. Mr. Philip Snowden said that he long ago came to grasp the importance of the public health side of local government. Whereas in Parliament one saw little if anything of the results of weary hours of debate, in local government one could see things being done. He paid a high tribute to the permanent officials of the country, and medical officers not least among them, for their loyal, enthusiastic, and able work. Speaking of the great attractions and opportunities of the public health service, Mr. Snowden declared that good salaries for good men were good economy; the

country, he said, could not afford to retrench in its expenditure on health services. Sir John Rose Bradford said that his presence at that gathering in the capacity of President of the Royal College of Physicians would show that there was no separation between curative and preventive medicine, and that the branch with which the Society was associated was one that every physician had at heart. The only thing that made him a little unhappy was the fear that if preventive medicine continued to forge so rapidly ahead, his present office might in time become obsolete!

#### ROYAL MEDICAL BENEVOLENT FUND'S CHRISTMAS GIFT.

It has been the practice of the Royal Medical Benevolent Fund for many years to present to the annuitants and some of the most necessitous grantees a Christmas gift of 25s. The Treasurer now makes an appeal for £370 to keep up this practice. The committee has not in hand any special fund to draw upon to meet this Christmas gift, to which the recipients in former years are no doubt looking forward. It is a gracious and friendly act, and we have no doubt that many readers will wish to make the continuance possible. Subscriptions may be sent to the Honorary Treasurer, Sir Charters Symonds, at the offices of the Fund, 11, Chandos Street, Cavendish Square, London, W.1.

An Association of Special Libraries and Information Bureaux has been formed in London, and is preparing, with the assistance of the Carnegie Trust, a directory of sources of specialized information in the British Isles. Membership is open to all interested bodies, and the subscription is two guineas a year. A copy of the directory will be supplied to members as soon as available. Further details can be obtained from the secretary of the association (38, Bloomsbury Square, London, W.C.1). In order to ensure the establishment of the scheme on an adequate scale it is hoped to obtain not fewer than five hundred members by March, 1927.

#### ROYAL MEDICAL BENEVOLENT FUND.

At the last meeting of the Committee fifty-eight cases were considered and £784 9s. voted to fifty-two applicants. The following is a summary of some of the cases relieved.

Widow, aged 59, of M.D. 1889 who died in 1914. She has three children. The son, aged 26, is in a mental hospital. The younger daughter, aged 22, is a probationer nurse, and the applicant is dependent on the elder, aged 23, who earns £2 a week as a clerk. Until three years ago the applicant maintained herself. Voted £26 in twelve monthly instalments.

M.D. Glas. 1885, a widow, aged 68, who retired on account of ill health and deafness. He now lives with a son who is a minister with a small stipend. A daughter earns £75 a year as a secretary. He asked for a grant to enable him to contribute towards the board of himself and his personal attendant. Voted £40 in twelve monthly instalments.

Widow, aged 58, of L.R.C.P.I. 1898 who died in 1904. Only income is rent from a house £65 per annum net. Has one room at a cost of £31 4s., including coal. No children. Insufficient income to cover necessities and clothing. Voted £10 in two instalments, and clothing.

Widow, aged 73, of L.R.C.P. Edin. who died in 1920. Her eldest son allowed her £20 a month until his death in January last. The second son is not in a position to make a regular allowance, but helps to the best of his ability. She has no other income. Voted £36 in twelve monthly instalments.

Widow, aged 54, of M.R.C.S. who died in 1924. Owing to ill health she is unable to work. She lives rent free in a cottage and receives the rent, 5s. a week, of an adjacent one. She has no other means, but has received poor relief. Voted £26 in twelve monthly instalments.

Widow, aged 55, of L.R.C.P. who died early this year; he was in receipt of an Epsom pension, the old age pension, and an annuity from the Fund, all of which ceased at his death. The applicant is now looking out for work. The Fund has voted £17 since May, and £18 in twelve monthly instalments from November 1st next.

Subscriptions may be sent to the Treasurer, Sir Charters Symonds, K.B.E., M.S., F.R.C.S., at 11, Chandos Street, Cavendish Square, W.1.

The Royal Medical Benevolent Fund Guild still receives many applications for clothing, especially for coats and skirts for ladies and girls holding secretarial posts, and suits for working boys. The Guild appeals for second-hand clothes and household articles. The gifts should be sent to the Secretary of the Guild, 53, Great Marlborough Street, W.1.

# AN EPIDEMIC OF POLIOMYELITIS IN ESSEX.

REPORT BY DR. BOUL, M.O.H.

THE town of Grays Thurrock, on the north bank of the Thames below London, has suffered during the present year from an outbreak of anterior poliomyelitis. There were 58 cases in all, and 11 of these have died. The population of the area affected is about 25,000. We are indebted for the following particulars to a report Dr. W. T. G. Boul, medical officer of health for Grays and Tilbury, has placed at our disposal.

It would appear that four patients sickened in Grays with poliomyelitis on widely spaced dates in May, 1926. Two of the four were not notified; they were discovered about two months later. During June and the early days of July no cases are known to have occurred. On July 6th a more active phase began. Two patients fell ill on that day and one on the day following. Then cases sickened on July 9th, 10th, 13th, and 18th—two on each; and there were single cases on six other days up to the end of the month, making a total of 17 cases for July. On August 3rd the outbreak reached its acme. On that day four patients sickened. On each of three other days in August three persons became affected. The total number of cases in August was 31. There were 6 cases only in September; the last fell ill on September 21st. The dates of sickening of the 58 cases, and the number on each day, are shown in the following table, which has been prepared from data contained in a report on the epidemic by the medical officer of health of Grays and Tilbury.

*Poliomyelitis at Grays, May 3rd to September 21st, 1926. Number of Cases and Dates of Sickening.*

## Missed Cases.

Of the 58 cases, 11 were missed, or delayed in notification. Of the 4 cases in May, 2 were missed; of the 17 in July, 6; of the 31 in August, 3; and of the 6 in September, none. The ratio of the missed to the total cases fell progressively month by month—a frequent experience during the currency of an epidemic when the public become alive to its danger. One missed case, a child which sickened on July 7th, was out and about in the town for ten days until isolated by the health department. During this time it infected one of its playmates, also a missed case, by whom the disease was distributed, directly or indirectly, to many.

Missed cases played a part also in keeping infection alive in a detached group of houses, which is situated at cross-roads on a building estate now in course of development in a new part of the town. Two cases here in July were followed, after an interval of three weeks, by three others. The gap, on investigation, was found to be bridged by two missed cases in adjacent houses, both of whom, when they came under notice, exhibited marked paralyses. As the missed cases were in the habit of playing with other children at the cross-roads there was ample facility for the transmission of infection. A similar localization, with one missed case, was observed in the old part of the town. Out of nine houses standing in a row three became infected, with 3, 3, and 1 case respectively in the several houses. The missed case, one of three in the family, was in the centre house of the row. The father of this family had himself suffered from poliomyelitis three years before, and showed permanent paralysis of one leg in consequence.

## "Real" and "Abortive" Cases.

The cases in the outbreak are divided by the medical officer of health into two groups, entitled "real" and

"abortive" respectively. The real cases, 39 in number, are those which developed the forms of paralysis characteristic of poliomyelitis. The abortive cases, numbering 19, had the symptoms of invasion only, such as fever, vomiting, and pain in the neck. The proportion of abortive to real cases was in May as 1 to 3; in July as 6 to 11; in August as 11 to 20; and in September as 1 to 5. From these figures no significant conclusion can be drawn. In view of the association of abortive cases with real cases to which they led up or on which they followed, their inclusion as cases in the sum total of the epidemic would appear to be warranted. Of the 11 fatal cases, 9 died after less than three days' illness; of the remaining 2, one died later of bronchitis, and one of a relapse of poliomyelitis with extension of the paralysis. The fatal cases remained fully conscious until near the close. "A peculiar movement of the muscles of the throat and floor of the mouth" was noted as a sign of impending death. Three patients who presented symptoms polioencephalitic in type recovered. None of the deaths occurred in July or in the early days of August, by which time 32 of the 58 cases had sickened. The maximum virulence of the disease, therefore, was not coincident with the period of rising infection.

## Age Incidence and Mortality.

Dr. Boul, in his report above referred to, comments thus on the age incidence and mortality of attacks:

"Of the 58 cases, 4 only occurred in adults, at the following ages: 17, 18, 22, and 36. Two of the adults died, a mortality rate of 50 per cent., but the numbers are too small for impor-

tance. The principal age affected was 2-3, where 13 cases occurred. The periods 0-1 year and 10-15 were comparatively free from cases. Whilst the general mortality rate is 19 per cent., the mortality rate at the age of 2 is 38 per cent."

## Signs and Symptoms.

The percentage frequency of the signs and symptoms observed was ascertained to be as follows: Fever 100, twitching 66, vomiting 62, pain in neck 48, pain in back 10, retention 10, pain in limbs 16, drowsiness 39, headache 20, diplopia 8, Kernig's sign 2, nystagmus 2, diarrhoea 4, sore throat 2. On symptomatology Dr. Boul remarks:

"With regard to the actual symptoms shown, a careful history of each case was kept by myself. The most constant symptoms are in the following order: (1) feverishness, (2) twitching, (3) vomiting, (4) pain in the back of the neck. The twitching may be general or confined to one portion of the body only. The vomiting usually occurs on the first or second day only, and it is rare for the patient to vomit more than three times. The speech was affected in three cases only, in one case of which the child had also sore throat and may possibly have been a diphtheritic paralysis, although a swab taken gave a negative result. Vesicles resembling varicella were seen upon the limbs of three of the children, but not until some few weeks after the initial illness. Prodromal symptoms occurred in two cases only."

## Diagnosis.

Dealing with diagnosis, Dr. Boul writes:

"The differential diagnosis is extremely difficult in the early stages. Cases of feverishness with vomiting are common enough in children of the age 2-3. An important point is the lack of intestinal signs. Apart from the limited amount of vomiting, pain in the abdomen and other signs pointing to an illness of intestinal origin are conspicuous by their absence. The most valuable symptoms are undoubtedly pain in the neck and back

and twitching, symptoms which do not occur in other childish disorders. The temperature is not usually high, and the lack of throat symptoms is important. The tongue is usually furred, but the breath not offensive as in complaints of intestinal origin. Very much has been written concerning the value of exaggerated knee-jerks. As a point of early diagnosis I am convinced that they are valueless. Exaggerated reflexes are common in many feverish disorders of childhood. The knee-jerk is often extremely hard to elicit in young children, a fact which may be confused with their absence, but two things are important: (i) exaggerated knee-jerk upon one day followed by lack of knee-jerk upon the next; (ii) a difference in the two legs. The knee-jerk is undoubtedly exaggerated in the early stage and lacking at a later date. Constipation was usual, but, contrary to the general opinion, nasal or pharyngeal catarrh was extremely uncommon. Retraction of the head occurred in about 10 per cent. of cases."

#### *Measures taken to Check the Epidemic.*

The methods adopted for the control of the epidemic were vigorous and comprehensive. Local practitioners were circularized and adjacent medical officers of health warned. The Ministry of Health was notified, and sent a medical officer to view the situation and advise. The throats and noses of contacts were sprayed with 1.5 per cent. hydrogen peroxide. Of the children sprayed one only contracted the disease. As the schools closed for the summer holidays the question of preventive closure did not arise. One case only was traced to school contact. Information and advice were given through the local press and by means of placards. Provisions of notable value were the opening of special wards in the isolation hospital for the reception of the sick and the reservation of beds in orthopaedic hospitals for them after-treatment where necessary.

#### *Conclusion.*

The Grays epidemic of poliomyelitis observed the rule of summer prevalence to which the disease generally conforms in England. It made no discrimination as between the new housing estate and the more crowded old quarters of the town. It was no respecter of social conditions or up-to-date sanitation. On the contrary, it struck hardest at the more well-to-do families. In 34 of the 58 cases the source of infection is believed to have been traced. Multiple cases in houses and streets were common, and the distribution of infected foci was general over the area concerned. The type of the outbreak was that of a communicable disease, spreading from person to person by contact or association through direct or intermediary channels. It has left in its track, at the date of Dr. Boul's report, 11 dead and 28 paralysed persons, with degrees of paralysis ranging from slight to complete. The dead and the maimed together amount to 39 out of 58 who fell sick; it is a casualty rate of 67 per cent. Happily this rate may yet be reduced by the orthopaedic treatment provided. There may be relief of the severer cases and cure of some of the milder. But in the end a residue must remain with varying grades of permanent incapacity—the usual aftermath of epidemic poliomyelitis, and its most formidable feature.

## EPIDEMIC ENCEPHALITIS IN SHEFFIELD.

### THE OUTBREAK OF 1924.

DURING the spring of 1924 a severe outbreak of epidemic encephalitis commenced in Sheffield as part of a pandemic which affected Western Europe, the United States of America, and Japan, as well as Great Britain. In this country, while every great town and many rural areas were affected, the highest attack rates were in Glasgow and Sheffield, the former city having 398 confirmed cases and Sheffield (with a much smaller population) 301. In London during the same year there were 541 cases, a figure greatly in excess of that of the previous year, though the case mortality fell from the high figure of 45.9 per cent. in 1923 to 22 per cent. in 1924.

On the suggestion of Professor F. E. Wynne, medical officer of health for Sheffield, and Professor A. J. Hall, the Sheffield Division of the British Medical Association convened a meeting representing all branches of the profession with a view to the institution of an investigation into

the local epidemic; a subcommittee was formed, including Professors A. J. Hall, J. S. C. Douglas, and F. E. Wynne, and Drs. J. Clark, H. Leader, J. McKinnon, J. Russell, and H. J. Egerton Williams, Dr. A. Gurney Yates being the honorary secretary. A wider scheme of investigation was also considered, as we mentioned on December 13th, 1924 (p. 1132)—namely, the formation of a permanent advisory committee to deal with any future outbreaks of epidemic disease, and such other conditions as cancer of the breast, in which the correlation of reports of the incidence and response to treatment might result in an advance of knowledge. The subcommittee which dealt with epidemic encephalitis met under the chairmanship of Professor Hall, who, with Dr. A. Gurney Yates, took charge of the clinical side of the investigation; the epidemiological inquiry was entrusted to Professor Wynne, and the pathological work was in the hands of Professor J. S. C. Douglas.

The report of this subcommittee has now been issued by the Medical Research Council.<sup>1</sup> The reports on the epidemiological, pathological, and clinical aspects of the epidemic are supplemented by an appendix by Dr. J. R. Perdrau, in which the problem of etiology is considered in the light of recent researches. A grant was made by the Medical Research Council towards the expense of the pathological work.

Although the critical study of this particular epidemic and the close and prolonged observations of individual patients have not directly solved the problems of etiology or indicated the lines on which effective preventive control may be established, yet valuable information was obtained, and it is clear that further work of this kind, in which the infection is studied from all available points of view by workers acting in close collaboration, will probably achieve success in the future.

#### *Epidemiological Report.*

Professor Wynne calls attention to the difficulty of drawing conclusions from the statistical reports of such a disease as epidemic encephalitis, in which the epidemiology varies so widely and the proportion of abortive or missed cases is therefore so high. The total number of cases notified as encephalitis during 1924 was 317, but sixteen of these were proved later to have been wrongly diagnosed; this represents an incidence rate of 0.57 per 1,000 of the population. In 45 cases death occurred, giving a mortality rate of nearly 0.09 per 1,000, the case mortality being 14.9 per cent. Of the total cases 58.4 per cent. occurred in males, but the fatality rate was slightly greater among female patients, in the proportion of 15.08 per cent. to 14.77 per cent.; these figures agree with those reported in other outbreaks of which accurate figures were available. There appeared to be an increased susceptibility to infection in males between the ages of 15 and 30 years, and Professor Wynne adds that if this is confirmed elsewhere it will tend to show that there is a greater susceptibility to infection in the central nervous system of the male as compared with the female during the period when sexual maturity is attained and is most active. No evidence was obtained pointing to any relation between the disease and social conditions, such as overcrowding, poverty, or insanitary dwellings, or of any association with topographical factors, or with the supply of water, milk, or any kind of food.

#### *Encephalitis and Influenza.*

The possibility of there being some relation between influenza and encephalitis received careful consideration. So far as the comparative incidence of the two diseases since 1918 is concerned there appears to be no very obvious connexion, and 1924 was not a period of exceptional prevalence of influenza in Sheffield. In the previous year there had been a slight recurrence of influenza, but the notifications of encephalitis were only about one-half of the numbers for 1920 and 1921. A definite correlation, however, emerged during the period of prevalence of the encephalitis epidemic; influenza deaths increased rapidly from the middle of January, 1924, while encephalitis began to become epidemic some six weeks later, reaching

<sup>1</sup> Special Report Series No. 108. H.M. Stationery Office. Is. 9d. net.

its peak, as a chart in the report illustrates, fourteen days after the influenza peak. From this time to the end of the year there is shown to have been an approximate parallelism between the curves, the encephalitis maxima occurring generally from one to three weeks later than the influenza maxima. Professor Wynno remarks that these results are particularly interesting in connexion with the suggestion of Mr. Lowndes Yates that influenzal infection of the accessory sinuses precedes the infection of the central nervous system by the encephalitis virus. On the other hand, it was found that, whereas there was a history of previous influenza in sixty-four cases of encephalitis, there was a history of sore throat in only nineteen. No reliable evidence was obtained that the disease was spread by direct contact, nor did any data emerge for computing the incubation period.

#### Pathological Report.

Investigations by the pathological department of the University of Sheffield included attempts to transmit the virus or toxins of the disease to rabbits and mice, necropsies, and the examination of specimens of the cerebro-spinal fluid collected during life. Professor J. S. C. Douglas reports that animals were inoculated with cerebro-spinal fluid from ten cases of epidemic encephalitis without showing during life any symptoms which could be ascribed to this disease, while *post-mortem* examination and histological investigations of the brain were similarly negative. Brain emulsions from patients who died were injected into animals without causing any symptoms of encephalitis or any specific histological change in the brain of the animals, thus confirming the common experience that the virus of this disease can only be conveyed to laboratory animals with great difficulty, if at all. The nasal cavities of thirteen patients were washed out with normal saline solution and bacteriological investigation was combined with animal inoculations. No symptoms of encephalitis resulted in any animals and no histological changes in their brains. Filtrates of faecal cultures were similarly negative. As regards *post-mortem* findings in thirteen patients who died from encephalitis, the associated lesions observed were: terminal recent infections of the lungs in ten cases; swollen mesenteric glands in six; recent slight infections of the alimentary canal in four cases; swollen spleen in four cases; granular kidney and pyelitis each in one case only. Professor Douglas regards these lesions as being accidental concomitants in the encephalitis, though in one case the lobar pneumonia appeared to be the actual cause of death. No important change was discovered in the brain except the frequent occurrence of slight congestion of the grey matter and less commonly oedema, but microscopical examination showed the presence of a small-celled infiltration, principally perivascular, in all cases except one. This change was very patchy in its distribution, and though not absolutely specific of encephalitis lethargica, is thought by Professor Douglas to be highly suggestive of it in the absence of other gross disease. In one patient, however, no small-celled infiltration was detected, although numerous sections from different parts of the brain were examined microscopically; the clinical manifestation of the infection extended over two months, and the absence of the typical small-celled infiltration is tentatively attributed to the healing of the original inflammatory changes in the course of time, the patient ultimately dying from lobar pneumonia. Cerebro-spinal fluid from thirty-six cases was examined and found invariably to be free from acid-fast and other bacteria, and to be sterile on culture; in only three cases was the albumin content increased, and in these the rise was explained by the presence of blood. The fluid reduced Fehling's solution in each case, but no quantitative determination of the reducing agent was made; in nearly every case the number of white cells was below 6 per c.mm. The epidemic had, therefore, the same pathological characters as those reported elsewhere.

#### Clinical Report.

Professor A. J. Hall and Dr. Gurney Yates preface their report with the statement that the 301 cases considered do not represent by any means the real extent of the epidemic. Many cases of encephalitis, even of a severe character, were otherwise diagnosed, and so were not

notified. A still larger number of very mild or abortive cases were so indefinite as to preclude diagnosis. The primary attack was mild in about half the cases notified and severe in one-fifth. Complete recovery was more common in the milder cases, though Parkinsonism was a more frequent sequel of attacks of the mildest character. The death rate rose above the average when there was definite fever and vomiting, and fell below it when vertigo was the prominent symptom. It was highest when acute disturbance of the respiratory mechanism was present, particularly polypnoea, and also in cases with acute mental symptoms. Headache was the most common symptom, and sleep disorders, ocular palsies, and various motor phenomena were frequent.

The initial symptoms included slight pyrexia, sore throat, lethargy, insomnia, diplopia, vertigo, and attacks of disorderly breathing, sometimes of the asthmatic type. In the more severe cases the clinical features varied widely, positive motor phenomena often dominating the picture, and frequently simulating those of chorea gravis. The rapidity of their succession and their violence often led to extensive excoriation of the skin of the trunk or limbs, and exhaustion. As a rule they did not last for many days, but were followed by lethargy; myoclonus, however, continued sometimes for weeks or months. Epileptic convulsions occasionally ushered in the attack. In cases which proved fatal from the acute onset the positive symptoms usually changed to negative manifestations, such as lethargy, stupor, gradually increasing coma, profuse sweating, and a rising temperature. In a small number of cases a scarlatiniform rash appeared in the first few days, more commonly in young children. The primary attacks are grouped in the report into mild, moderately severe, and severe. A distinction is made between general symptoms, such as pyrexia, headache, vertigo, and vomiting, and indicator symptoms, including lethargy, with ocular palsies; insomnia with delirium; severe pain other than headache; and abnormal muscular movements.

#### Sequelae.

A questionnaire was issued in August, 1925, at the instance of the Medical Advisory Committee of the Sheffield Division of the British Medical Association in regard to those patients who had survived, and the results obtained include the following.

Ocular palsies rarely persisted, except in minor degree, but speech defects, though rare, might remain troublesome for a long time. Ocular palsy in association with sleep disorder seemed to have a favourable prognostic significance. Vertigo, when present in the primary attack, tended to disappear, but occurred first as a sequel on several occasions. Severe neuralgic pains only persisted in one-sixth of the cases in which they were present, and mental disorders continued in a modified way in half the cases in which they were acute in the primary attack. On the other hand, more cases are recorded as having mental residua at the end of the 1925 than the few in which they had persisted from the start. The form of sleep disorder present in the primary attack was found likely to be the form in which it persisted, if it did so at all. When insomnia occurred alone in the primary attack it tended to persist, but sleep disorder, in the form of nocturnal insomnia usually, might first appear as a sequel. No definite conclusions in respect of moral changes were reached: as a rule they were not clearly noticed until the patients resumed ordinary life after the conclusion of the primary attack. Respiratory disorders occurring during the onset did not persist; those appearing as sequels were very varied and not infrequently associated with nocturnal restlessness and Parkinsonism. They were more common in males than females, and the average age of the patients was about 15. This is in marked contrast with primary respiratory disturbances, which were found more often in females than males and had an average age of 28. Parkinsonism was much more common in males than females; it occurred chiefly during the age period 15 to 35, but did not seem to have any tendency to produce sterility in women. In more than one case pregnancy occurred during the disease, the patients usually having normal children after an easy, straightforward

labour. Pregnancy, however, appeared to have a very prejudicial effect on the course of the disease. In the male complete impotence was not uncommon. Parkinsonism usually commenced about six to twelve months after the primary attack, and there was no evidence that the prognosis was better if it occurred early. The facial mask was the most common symptom and usually the earliest to appear; next to this came involvement of the upper limbs, in approximately equal numbers on the right and left sides. The conjugate movement of the eyes was sometimes disturbed, recurrent attacks occurring in which the eyes were involuntarily turned upwards, usually to one or the other side, and remaining fixed for a variable time, perhaps several minutes. Spasms of the jaw muscles also sometimes occurred and interfered with eating. These attacks came on without obvious cause at irregular times. Five out of 64 patients with Parkinsonism died, and of the remainder 19 appeared to be getting steadily worse, while about 23 were at a standstill. Of the 43 fatal cases in the whole series, death occurred in 40 within two months of the onset of the disease; of the remaining 3, 2 died of pneumonia several months after the primary attack, while one boy died eight months after a mild attack, which was followed by what appeared to be a recurrent acute attack with profound lethargy.

#### *Etiology of Encephalitis Lethargica.*

Dr. J. R. Perdrau of the National Institute for Medical Research contributes a short report of parallel work in London in close association with the Sheffield outbreak. He supports the contention of Levaditi and others that the causal agent of epidemic encephalitis is identical with that of herpes febrilis, except that the former has a greater affinity for the central nervous system. He admits that this theory of the herpetic origin of epidemic encephalitis is not universally accepted, though no other theory has so far been propounded on experimental grounds. A detailed account of his work was published in the *British Journal of Experimental Pathology* last year.

### THE CARE OF CRIPPLED AND INVALID CHILDREN.

A JOINT conference under the auspices of the Invalid Children's Aid Association and the Central Committee for the Care of Cripples took place in the Great Hall of the British Medical Association House, Tavistock Square, on Thursday and Friday, November 18th and 19th. The conference, which was very largely attended, had for its general subject the care of crippled and invalid children, and in four sessions the particular phases of the subject dealt with were (1) a general survey of the work for invalid and crippled children, (2) the preventive side of cripple work, (3) the need for unity of effort on the part of local authorities and voluntary workers, and (4) the question of the physically defective child in school and after school.

Lord EUSTACE PERCY, President of the Board of Education, delivered the inaugural address in the absence of the Minister of Health, who, as Mrs. Neville Chamberlain told the conference, was detained by his work on the smoke abatement measure, which he was pressing through the parliamentary committee. Lord Eustace Percy remarked that at most only one-quarter of the crippled children of this country were provided for in the special schools and clinics, and there were 200 areas in which no provision was at present made. The key to the whole position was the provision of new hospital accommodation for orthopaedic cases, and the main burden of such provision, though not necessarily the whole, must, he thought, fall on voluntary effort.

Mr. R. C. ELMSLIE, who opened the first discussion, gave a rapid survey of the work in this country on behalf of the crippled. He said that of the forty English counties practically all had been considering the formation of schemes for the care of cripples; in 13 there was as yet no definite scheme of any sort, and in the remaining 27 some sort of scheme was in hand, often, however, incomplete. In Wales the National Memorial Association had set aside a considerable number of beds for surgical tuberculosis, and Sir

John Lynn-Thomas was intent upon organizing a general scheme for the care of the non-tuberculous cripple, the central hospitals being the Prince of Wales's Hospital at Cardiff, for South Wales, and the Oswestry Orthopaedic Hospital, for North Wales. In Scotland much was being done by local authorities and voluntary bodies, but there was an absence of central organization.

Mr. HARRY PLATT of Manchester followed with some account of what is being done in America and on the Continent. He described particularly what is known as the Vermont organization in America for the early treatment of infantile paralysis in epidemics. This organization, he said, included adequate measures to control the spread of infection, and the institution of early treatment for children who showed actual paralysis, with the establishment of special clinics in infected areas, and arrangements for home visitation and for operative treatment in hospital.

Sir ROBERT JONES, Bt., chairman of the Central Committee for the Care of Cripples, in speaking of future developments, described at some length the work of that organization in the directions of prevention and cure. He said that the national scheme included the provision of open-air orthopaedic hospitals, with expert staffs and modern equipment, and, surrounding these, orthopaedic clinics in the smaller towns, by which it was hoped to ensure continuity of treatment. He advocated an intensive publicity campaign, especially with the object of making it known that tuberculosis and rickets were preventable, that crippling diseases were not hereditary, but acquired and gradually progressive, and that generally they were curable by well organized, early, skilful, and thorough treatment. Future developments should not disregard the claims of the adult cripple. At present if the cripple was over the age of 14 or 16 it was next to impossible in this country to afford him adequate help. The desire to help and the requisite knowledge were available, but the facilities were absent. The adult cripple had a right to expect from the State equally considerate treatment to that which was given to the child, and beds should be available for him. Sir Robert Jones pleaded for more optimism with regard to this whole subject, and an end to the despair and consequent lethargy which had shrouded it.

Dr. VEITCH CLARK of Manchester said that 33 per cent. of children had some defect on entering school, not always, of course, of the crippling variety, but leading very often to incapacity, partial or complete, later on. In Manchester last year he received notification of about 500 new cases of tuberculosis in children under 15 years of age, at least one-half of them of the surgical type. The conditions which produced rickets also operated most seriously in the great industrial centres. Dr. ALFRED GREENWOOD described the successful inauguration of a scheme which, as medical officer of health for Kent, he had brought forward in that county, and the way in which he had allayed certain misunderstandings among the local practitioners who were a little distrustful of what they regarded as a new special service.

At the second session papers were read on rickets, on rheumatism, chorea, and heart disease, and on tuberculosis from the preventive point of view. Dr. STUART J. COLWELL of Sheffield, in discussing rickets, said that it had been stated that rickets was a rare disease in London, but recently published statistics hardly bore out that optimism, and certainly in most industrial centres this crippling disease was still rampant. The measures of treatment were a proper supply of antirachitic vitamin, and, alternatively, or in addition, treatment by ultra-violet radiation, and, of course, attention to general health. Dr. ARTHUR STEPHENS, chairman of the Swansea Education Committee, said that there were from 80,000 to 100,000 cardiac cripples under 14 years of age for whom little or nothing was being done. Bad feeding and malnutrition were the predisposing causes. A family history of bad cookery was of far more serious import than a family history of supposed hereditary rheumatic disease. Cardiac cripples could be treated to the best advantage, alike physically, mentally, and economically, in conjunction with orthopaedic cripples. The ultimate solution of the problem of prevention was bound up largely with the land-problem

and the home cultivation of food, with less complete reliance on imported food products. Dame AGNES HUNT, of the Shropshire Orthopaedic Hospital, also read an interesting paper on tuberculosis, discussing the subject from the point of view of district nursing.

At the third session, under the chairmanship of the Hon. Sir ARTHUR STANLEY, the advantages of official and voluntary effort were compared. Dr. C. E. TANGYE, medical officer of health for Wiltshire, discussed the role of local authorities in an orthopaedic scheme, and related the events in his own county. While himself warmly supporting official health work, and rebutting the criticisms that it was unsympathetic, niggardly in action, and extravagant in administration, he agreed that it would be folly to ignore the freely offered services of voluntary workers, and there was also a third partner—namely, the general practitioner—without whose collaboration the best results could never be obtained in any official scheme. Mr. G. R. GIRDLESTONE of the Wingfield Orthopaedic Hospital, on the other hand, advocated the voluntary hospital and clinic, with a staff honorary or paid on a part-time basis. One advantage was that members of such an honorary staff would in the ordinary way hold specialist orthopaedic appointments at the general hospital of the district, and this would mean close co-operation between the orthopaedic and the general hospitals. One of the great drawbacks of the purely official scheme, in his view, was that when the patient was over school age, unless he was tuberculous, the doors were closed to him. There was a good discussion, but no great cleavage of opinion developed, the idea being that every means, official and voluntary, should be adopted as far as possible.

At the final session the question of the physically defective child in school was considered from various points of view. Mr. K. J. ACORN DAVIS, of the L.C.C. physically defective schools, gave the point of view of the surgeon. The aims with which he set out were: (1) to improve the physical condition of the child; (2) to produce persons capable eventually of earning their own living; (3) to protect the children from getting damaged by accidents. He also pleaded for the linking up of the welfare centres and the schools. There was a gap at present between the age at which a child was taken by its parents to the welfare centre and the age at which it arrived under the care of the education authorities, and it was in that gap that the maldevelopment was often missed.

Papers on the same subject, from the point of view of the school manager, the matron, and the teacher, were read by three ladies, and the question of the physically defective child after school was discussed by Sir MONTAGU BURROWS, chairman of Wingfield Orthopaedic Hospital. The discussions throughout the two days were very fresh and stimulating, and will be of great service to the two organizations which called the conference, but the constitution of the conference itself precluded any effective resolutions.

## ROYAL SOCIETY OF MEDICINE.

### THE PRIME MINISTER AT THE ANNUAL DINNER.

THE annual dinner of the Royal Society of Medicine took place at the Hotel Victoria on November 18th, when a company of 450 sat down at the tables under the Presidency of Sir JAMES BERRY, F.R.C.S. The society was honoured by the presence of the Prime Minister (the Right Hon. Stanley Baldwin), and among the other principal guests were:

Sir Berkeley Moynihan (Président, Royal College of Surgeons), Sir StClair Thomson (Immediate Past-President of the society), Sir Ernest Rutherford (President, Royal Society), Sir Humphry Rolleston (President, Medical Society of London), Mr. R. G. Hogarth (President, British Medical Association), the Master of the Apothecaries Society, Dr. Christine Murrell (President, Medical Women's Federation), the Presidents of the Geological Society and the Royal Geographical Society, the Presidents of the Hunterian, Harveian, West London Medico-Chirurgical, and Chelsea Clinical Societies, and Professor J. S. Haldane, F.R.S. (the Society's Gold Medallist).

The PRIME MINISTER, in proposing the toast to the society, said that he had been impressed by the extraordinary way in which all medical knowledge and practice

was embraced under the single title of the society. He had read with much interest the society's calendar, and he could not help thinking how proud Sir Andrew Clark would have been had he lived to see the day when the society took its present shape, for Sir Andrew had desired to bring together the profession, for their common help in all investigations in the various departments of medicine, and to provide a common centre for the collection, co-ordination, comparison, and criticism of their respective researches. Nearly twenty years ago seventeen separate medical societies went to sleep for a moment, and when they recovered consciousness found themselves thirteen separate sections of the Royal Society of Medicine. Since then the thirteen had grown to twenty-four. The names of most of them conveyed no clear idea to his mind, though one of them struck a responsive chord, for it bore the name "Parasitology"! He compared the constitution of the society to that of the British Empire, with autonomous parts, bound together, not by a crown, but by a library, which he trusted was more interesting than that in the House of Commons.

Mr. Baldwin went on to discuss certain points of similarity between the medical profession and the profession of politics. Both professions owed a most profound debt to the Greeks. He had lately read a fascinating little book in which there was an article by Dr. Charles Singer, and it had been a revelation to him, interested as he had always been in Greek thought, to be told by a scientific man what a debt his own branch of science owed to that great and remarkable people. Dr. Singer stated that the teaching in the wards of a modern hospital was based on that of the Greeks, and that Greek medical literature was full of evidences of really fine scientific effort. To most the great Hippocrates had been only a name, but he was evidently a personality who stood to-day as he stood then for learning, humanity, gravity, and—a quality which the speaker held in the highest esteem—reticence; in these respects Hippocrates must ever remain the type of the most perfect physician. (Applause.)

Throughout his life (Mr. Baldwin continued) he had been singularly unfortunate in having seen so little of members of the medical profession. But a great deal of the doctor's work stood a close comparison with that of the politician. Both the medical man and the politician were physicians, though he preferred the medical man's patients to his own. He himself had been trying to prescribe for some time, with complete failure. The goal which they shared was a very simple one—to try to attain perfect health, involving a normal balance of the functions, a harmonious co-operation of all the organs, whether of the State or of the body. The State was an infinitely complex assembly of growing structures never at rest. The cells that composed it were always being born and always dying, but throughout the change there was a moving equilibrium of the whole. It was subject to considerable variations in temperature. Had a clinical thermometer been applied to the constitution in the early weeks of last May it would have registered a temperature of 105° or 106°, and though this had abated, there were symptoms of fever still in the body politic. A very virulent epidemic was abroad which might perhaps be diagnosed as Russian influenza. (Laughter.) It was not endemic, but epidemic, and yet epidemics lasted for a few seasons, though he believed they had a tendency to become less severe. A Harvey was wanted in the political world to find out the mysteries of the cyclical ebb and flow of unemployment. He did not think that surgery was needed, though there were people in politics who were always willing to resort to the knife, and would remove the House of Lords like an appendix. At the other extreme there were quacks and charlatans who sought to heal the sick by magic formulas, which they called slogans, exactly as the Romans used to try to set fractures by reciting meaningless phrases over the broken bones. One other thing he would say, with bated breath, that physicians, like politicians, sometimes had trouble with those members of their honourable profession who would not, or constitutionally could not, keep out of the press! This was a malady that broke out in the most unsuspected quarters. The profession of medicine had one advantage over that of politics. The medical man received emolu-

ments appropriate to the confidence reposed in him by the public, but the politician did not. If any politician did, his salary would vary remarkably with events and seasons.

"One other personal confession I should like to make," said the Prime Minister in conclusion. "I have sought some medical assistance in the course of the year, and I should like to give you my own experience. I expect you all know your Samuel Butler pretty well, and you may remember the physician in *The Way of All Flesh*, who prescribed for Mr. Pontifex—whose symptoms somewhat resembled mine, he was feeling tired—a course of the larger mammals at the Zoological Gardens. This physician, 'one of the most eminent doctors in London,' said:

"I have found the Zoological Gardens of service to many of my patients. I should prescribe for Mr. Pontifex a course of the larger mammals. Don't let him think that he is taking them medicinally, but let him go to their house twice a week for a fortnight, and stay with the hippopotamus, the rhinoceros, and the elephant, till they begin to bore him. I find these beasts do my patients more good than any others. The monkeys are not a wide enough cross; they do not stimulate sufficiently. The larger carnivora are unsympathetic. The reptiles are worse than useless, and the marsupials are not much better. Birds again, except parrots, are not very beneficial; he may look at them now and then, but with the elephants and the pig tribe generally he should mix just now as freely as possible."

"During the long and weary months of the coal stoppage I more than once escaped into Regent's Park, and became aware of a feeling which I had not experienced during my conferences—in Mr. Pontifex's own words, I received an influx of new life, or derived new ways of looking at life, which is the same thing. I found the doctor quite right in his estimate of the larger mammals as those most beneficial. As for the elephants, especially the baby elephants, I seemed to be drinking in large draughts of their lives to the recreation and regeneration of my own. I mention this in the hope that one or other of my hearers may find the hint useful."

Mr. Baldwin then gave the toast, saying what profound respect he had for the medical profession—a profession in which more was freely given to the people of this country out of the largeness of its heart and out of its wisdom and experience than from any other profession in the world, and those who rose up and called it blessed were beyond all enumeration.

Sir STCLAIR THOMSON then invested the President with a gold chain of office which he presented to the society. It was, he said, some three hundred years old, of the Elizabethan period, and doubtless wrought by some Italian artist, some Benvenuto Cellini of the Renaissance. He had had the benefit of the expert advice of the South Kensington Museum and of his friends Sir Frank Dicksee and Sir George Frampton, who had agreed as to its period and its artistic value, and that it was worthy of being offered to the Royal Society of Medicine, and the Council had honoured him by accepting it.

Sir JAMES BERRY expressed thanks to the Prime Minister for the felicitous terms in which he had proposed the society's health, and to Sir StClair Thomson for the valuable gift of one of the most beautiful chains in London. The chain would serve to remind them of their immediate Past-President, whose generosity was equalled only by his brilliance and wit. Sir James Berry then gave some account of the work of the society during the year. Many useful discussions had taken place, and improvements had been made in the internal arrangements of the society's house, especially by the provision of a new epidiastroscope (or episcope, as the makers called it), superior to any instrument of the kind hitherto known. The balance of the money subscribed as a memorial to the late secretary, Sir John MacAlister, had been expended on its purchase. Sir James Berry also referred to the value of the society's library, and in view of the lending and other facilities offered by the library made an appeal to general practitioners, especially those in the provinces, to become Fellows. He concluded with a few words on the present state of surgery. One of the many evil after-effects of the war was that a great wave of well-meaning enthusiasm for operative surgery had spread over this and other countries. Many difficult and dangerous surgical operations were being too lightly undertaken by those whose training, experience, and judgement were

insufficient, and who were not devoting themselves exclusively to the practice of surgery. Those who were behind the scenes in the surgical world saw only too much of what was going on. Successful major operative surgery in civilian practice must depend upon a solid foundation of pathological anatomy and clinical experience. The limited field of war surgery, necessarily concerned mainly with the surgery of injuries in more or less healthy individuals, was in itself alone but an indifferent school for the surgery of civil practice. The only remedy for this state of things was an increase of knowledge among would-be operating surgeons. One way of obtaining this increase of knowledge would be by joining the Royal Society of Medicine, attending as often as possible the debates and demonstrations, and making full use of its library.

The only other toast was that of "The Guests," which was proposed by Dr. ROBERT HUTCHISON. In a happy reference to the Prime Minister Dr. Hutchison said that Mr. Baldwin might have been even more in his element as a country doctor than as a politician. He would not have made a good specialist—he was too honest for that!—but with his love of the country and of country people and things, and his sympathy for the common man, he would have made an ideal country practitioner. He coupled with the toast the names of Sir William Bragg, Fullerton Professor, Royal Institution, and Sir Berkeley Moynihan, describing the latter as a sort of surgical "Pooh-Bah." Sir Berkeley, he said, must find it, as President of his famous College, somewhat of a bore to attend so many official dinners, but in his private capacity it must afford him a certain satisfaction to see laid broad and deep before his eyes the foundation of those dyspeptic disorders which brought so much grist to his mill. (Laughter.) In Yorkshire, a county whose people were supposed to be somewhat addicted to the pleasures of the table, they had two gifts of Providence—the waters of Harrogate and Sir Berkeley Moynihan. If the first failed, the best they could hope for any patient was that he might fall into the arms of the other.

Sir WILLIAM BRAGG said that it was the greatest happiness of any man doing research work in science to feel that he was of any help to those who were responsible for the health of the nation. Science on his side had to thank medical men for assistance. Indeed, medical men and scientific men—that is, chemists and physicists—had been in partnership for the last 250 or 300 years. They were, so to speak, boys together during the last half of the seventeenth century, when the times were full of scientific experiment, when wonderful theories were abroad, and when the Royal Society was founded. In these days, when it was possible to look more deeply into Nature's secrets than ever before, he hoped that they might still render one another great service.

Sir BERKELEY MOYNIHAN took up Dr. Hutchison's allusion to him as "Pooh-Bah," and amusingly pictured himself occupying the various offices of that distinguished gentleman, and said what he would do in each, until at last he recalled that Pooh-Bah was also commissioner of police, and in the exercise of that office he arrested himself for loitering. Sir Berkeley Moynihan went on to pray for a closer understanding between the lay public and the members of the medical profession. There was not a gregarious profession, and they were apt to be silent under attack. But they were wounded in the house of their friends when those who knew them took distorted views of their work and ideals. How little they were sometimes understood was shown in the earlier months of this year when the profession was bitterly assailed in private speech and in the public press. Prejudice seemed then inordinately bitter against them, but prejudice was nothing but the emotional reaction of ignorance to truth, and truth in the end had a way of surviving. But he pleaded that members of the profession should do all in their power to present the plain truth acceptably to the public on due occasions, to play a larger part in municipal and national affairs, and to endeavour to saturate public life with the ideal of service and sacrifice.

The last event of the evening was the presentation of the Gold Medal of the society to Dr. J. S. Haldane, F.R.S. This medal is awarded every five years to a

scientific man or woman who has made valuable contributions to the science and art of medicine. It was the gift of the late Dr. Murray Leslie, and the first award was made in 1921 to Sir Almroth Wright. The medal bears on its obverse a representation of Hygieia, daughter of Aesculapius, bestowing a wreath upon Research, while the reverse represents Chiron teaching Aesculapius the art of healing.

Dr. HALDANE, after thanking the Council for the bestowal of the medal upon himself, said that though his life had been given to physiology he had never failed to retain a keen interest in clinical medicine. As a physiologist he had very early in life discovered that the best subject of experiment was a human being, and that of human beings the best subject was either oneself or a brother physiologist.

## ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

### LORD BALFOUR AT THE ANNUAL DINNER.

THE annual dinner of the Royal Society of Tropical Medicine and Hygiene was held at the Hotel Victoria, London, on Monday, November 22nd. Dr. ANDREW BALFOUR, President of the society, was in the chair, and the principal guests were the Earl of Balfour, K.G., O.M., the Hon. W. Ormsby-Gore, M.P. (Parliamentary Under Secretary for the Colonies), Sir Joseph Cook (High Commissioner for Australia), Sir John Rose Bradford (President, Royal College of Physicians), Sir James Berry (President, Royal Society of Medicine), Sir John Bland-Sutton, Sir Walter Fletcher (Secretary of the Medical Research Council), Surgeon Vice-Admiral Sir J. Chambers (Medical Director-General, R.N.), and Lieut.-General Sir Matthew Fell (Director-General, A.M.S.). The company of 200 was representative, not only of tropical medicine, but of all branches of medical science.

The EARL OF BALFOUR, in proposing "The Royal Society of Tropical Medicine and Hygiene," referred to the problems presented to the country by the tropics, in which the expert and the inexpert alike were deeply interested. Looking at the problems from their national and imperial aspects, he was profoundly struck by the growing closeness of intimacy between all forms of human activity. Not many years ago the spheres of human activity were separate; in practice the man of science was either a physicist, an astronomer, or a chemist; the word "biologist" had not become fashionable at that time. A doctor who was a man of observant habits visiting Africa, for instance, came back with much useful knowledge, but things were not considered in their interrelation. If everything had to be regarded in the light of modern knowledge, interconnected and getting more and more interconnected every day, how were problems of such increasing complexity to be dealt with? Anyone who followed what had occurred at the Imperial Conference would agree that the section which had had entrusted to it the consideration of such problems showed the keenest appreciation of the need for growing intercommunication in all scientific branches of study. One important problem was that of the tsetse fly in Africa. It was an appalling reflection that, looking back over the history of mankind, people should have to say that the greatest of all prehistoric discoveries, the discovery or creation of the domestic animal, over a vast area of Africa was rendered impossible because such animals could not be used for transport owing to the all-conquering tsetse fly. It had been said by our ancestors that man was the crown of creation, but man was having a very hard fight of it with organisms which were certainly not the crown of creation, and it was not perfectly clear to him as yet that man was getting the best of the fight. There were aspects of medical science which almost indicated that at the present moment the battle was not going in favour of the superior animal. If that was true what was needed was a combination of all branches of science, and the work of a society such as this was a necessary part of the machine. A man who took a medical degree and went out to a remote part of the Empire found himself face to face with tremendous problems, not only strictly medical

problems, but also problems of anthropology, which could not be ignored by anyone who tried to deal with the native races. He found himself forced by his own sense of the necessity of the situation to do research, while at the same time often overloaded with routine work. He discovered very few companions who either understood the objects for which he was working or his methods, and therefore the society was of immense advantage to him, not only by furnishing him with its transactions, but because he could feel himself part of a great machine which was attempting to deal, in a broad spirit, with all these problems, and that when he came home he would find in the society those who could help him in his troubles. Lord Balfour wished the society long life, great success, and an increased sphere of usefulness.

In replying to the toast, Major E. E. AUSTEN, of the Department of Entomology in the British Museum, made a strong plea for funds to enable the society to have a house of its own in London, and so develop its activities in a way which it could not do now in its cramped temporary abode.

The toast of "Britain in the Tropics and its Defenders" was proposed by the Hon. WILLIAM ORMSBY-GORE, M.P. He said the outposts of the Empire, the Dominions, and Colonies, stretching from the torrid zone, had ever before them the special problem which interested the workers associated with this society. But it should be remembered that the British Empire would never have existed, and could not exist, were it not for the physical defenders typified in the other guests who were to respond to the toast. In the past our young men went out to the tropics carrying their lives in their hands, and even to-day the odds were not quite what they ought to be, and the risks were great both to health and life. It was being realized to-day that the health of our garrisons, of our civil servants, and of traders in the tropics could not be maintained, apart from the health of those teeming millions who were living in those countries. Where problems of science and disease had to be considered it was not possible to draw national boundaries. The health of the British in the tropics was bound up with the health of their coloured fellow-subjects. Britain would never bring to the use of civilization and to the advancement of mankind as a whole the enormous resources of the tropics unless she could forward in quality of civilization and in health the interests of these coloured peoples. The task was only just beginning. It was due to the teachings of Manson and Ross that it was realized that garrison service was not enough, that the duty of Britain in the tropics was to the whole population. Above all, what was wanted in the great fight of man against insect was speed and mobility. Delay was dangerous, and foresight essential. What was needed in the tropics was the application of science, science, and more science. It was necessary to take a long view, such as the navy took when they said they were going to lay down a programme for many years ahead. The great fault in the past in dealing with British tropical possessions had been timidity, the short view, and the neglect of science. We had the greatest tropical Empire the world had ever seen, but it was difficult to get people to realize it.

Sir JOSEPH COOK, in reply, referred to the situation in Australia and the Pacific, and said that the problem of civilization in the tropics seemed to him essentially one of health, and if that were solved economic problems were solved straight away. Nothing hindered economic success in the tropics but the question of disease and insects, and he wondered whether it would not be possible to develop a type of manhood which would acclimatize itself to the tropics of the world.

The toast was replied to also by Sir JOSEPH CHAMBERS, who paid tribute to the successes of the professors of tropical medicine in London and in other places, and also to the work of the great Colonial Secretary, Joseph Chamberlain. Lieut.-Colonel W. P. MACARTHUR proposed the toast of "The Guests," which was responded to by Sir JOHN BLAND-SUTTON, who thought there had been a slight mistake in labelling the toast "Guests," because in such a society the toast should have been "Hosts and Parasites"! "The Chairman" was proposed by Sir MATTHEW FELL, who paid a tribute to the work of

Dr. ANDREW BALFOUR, especially in connexion with the Advisory Committee that visited Mesopotamia in 1916. The CHAIRMAN, in responding, referred to the good work done for the society by its honorary secretaries, Dr. Wenyon and Lieut.-Colonel Clayton-Lane.

## Canada.

[FROM OUR SPECIAL CORRESPONDENT.]

### TUBERCULOSIS IN CANADA.

DURING the present year great activity has been shown in connexion with tuberculosis. Some figures of a general nature may be of interest. Canada is made up of nine provinces, whose population in 1925 was 9,352,000; all the provinces possess regular death registration bureaux. In 1925 the total number of deaths from pulmonary tuberculosis was 6,257, and in the same year, for all forms of tuberculosis, 7,468. The death rate for tuberculosis per 100,000 was 79.8; the corresponding rate in 1924 was 83.28. This is a record which may well cause gratification, especially when it is recalled that at the time of the organization of the Canadian Association for the Prevention and Treatment of Tuberculosis, in 1901, the death rate from tuberculosis was 180. Acknowledgement is made, however, of influences both from Great Britain and the United States, the most recent being the visits by Sir Henry Gauvain and Professor Lyle Cummins. These two outstanding authorities addressed medical groups of eight provinces, and I can testify to the interest with which they were followed. Professor Cummins, in particular, brought out his experience in connexion with sanocrysin. Work in the maritime provinces (Nova Scotia, New Brunswick, and Prince Edward Island) has been given an extra stimulus by a gift from the Canadian life insurance companies of 45,000 dollars. The degree to which the Provincial Governments are ready to co-operate with the various provincial tuberculosis leagues is one of the most encouraging features of the situation; in New Brunswick, for example, there are hopes that the Provincial Cabinet will give its sanction at an early date to the addition of sixty-five beds to the Jordan Memorial Sanatorium. The Sanatorium Commission has over 100,000 dollars available for this work, but the Government's approval is required, because the Government becomes responsible for the increased maintenance. A committee from the Cabinet has visited the sanatorium, and has instructed the architect to revise the proposed plans. The medical profession of the province entirely support the tuberculosis movement, and many of them in the rural districts personally see that their municipalities provide institutional care for needy cases.

In Nova Scotia the Tuberculosis Commission has been granted 10,000 dollars by the Government for this year, and the money is being used to provide an extra diagnostician, a secretary, and a bacteriologist. The press has been giving hearty support, and the profession generally is entirely in accord with the plans. One of the first moves was made by the agricultural group, whose aim it is to rid the province of bovine tuberculosis. To this end an education train traversed the province last summer with exhibits and literature, and carrying speakers on the subject.

A special study is being made by Professor H. W. Hill of conditions among the Indians in British Columbia, the association having been given a grant for this purpose. The statistics for tuberculosis in this province have been showing in the last four years a grave increase, especially in comparison with other provinces, but it has been pointed out that this is due chiefly to the increasing percentage of deaths registered among North American Indians. In 1924, for example, they contributed 24 per cent. of tuberculosis deaths. Dr. Hill's work, therefore, is of great importance. The field covered by him is very extensive, and his report should be interesting. Apparently, sources of tuberculous infection are not hard to find, but cow's milk is not an important factor, as it is not used at all. Dr. Hill, in addition to his researches, addresses the Indians, and in some instances has induced them to vote as to the methods of care they favour.

### RESENTMENT AGAINST LIQUOR SYSTEM.

A forcible protest has appeared in a recent issue of the *Nova Scotia Medical Bulletin* with regard to the control of liquor in that province. The ground taken is that the profession has been imposed upon (he speaks colloquially of "being made the goat") by the local Government, in being made the sole medium through which the public can obtain their supplies of spirits. He describes the all too familiar scene of streams of visitors at his office, each one pulling out his dollar fee and making the laconic demand "Scrip, Doc." It is, he says, to be deprecated that money could be made out of it—even, if so desired, large quantities of it. However, those apparently acute troubles are over, since supplies of alcoholic liquors are much more freely obtainable from "bootleggers," leaving the doctors fewer prescriptions to write. But further aggravation has been caused by the recent instructions from the Liquor Commission to the medical profession making it necessary for those issuing prescriptions to make affidavit every quarter of the number issued. The point is well taken. It illustrates one of the less obvious results of prohibition. Each province in Canada has its own method of controlling the sale of liquor, and it is to be presumed that each separate plan is the expression of the majority's desire, but there seems to be little doubt that the method of controlling the sale in the province of Quebec is producing the most orderly distribution. There is in Quebec a Government liquor commission at whose shops alone liquor may be obtained (with the exception of licensed establishments for beer and light wines), and this relieves medical men of having to make special prescriptions for alcohol, with all the undesirable features that this involves. The profit made by the province is naturally high—enviably so in the eyes of some other provinces; but certainly no more excess is seen in this province than in those with complete prohibition of alcohol.

### RABIES IN QUEBEC PROVINCE.

An outbreak of rabies occurred in the region of Ottawa last winter, initiated by the bringing of two infected dogs from the State of New York. In spite of the prompt measures taken by the health authorities, the disease reached the island of Montreal. The efforts made to control its further spread from here were at first extremely vigorous; a muzzling order was issued, and thousands of stray cats and dogs were destroyed on the streets. The fact also that the bridges from the island could be watched to prevent dogs being taken off the island made the control of the infection fairly simple. Clinics were established at the city hospitals for providing antirabic treatment, and most dog-bites, of any type whatever, were treated there as a routine. No human deaths have been reported. It is hoped that with the advent of the winter the infection will be eventually stamped out, but the provincial health authorities quite realize how stringent and prolonged the precautions must be. Considerable numbers of infected cattle have had to be destroyed.

## England and Wales.

### A MILK CONFERENCE.

MILK in relation to public health was the subject of a conference convened by the National Clean Milk Society, and held in London on November 16th. It was announced that some thirty-four organizations, including the British Medical Association, supported the conference; and the Minister of Health, Mr. Neville Chamberlain, presided at the earlier part of the afternoon session. Notwithstanding these distinguished auspices, and a very good attendance at the meetings; it was hard to discover much that was new in the speeches. It was noticeable, perhaps, that the supporters of pasteurization appeared to outnumber the advocates of clean raw milk, thus reversing the position taken up at the discussion in the Sociological Section of the British Medical Association's Annual Meeting at Bath in 1925. At the morning session, in the discussion on Dr. Harriette Chick's paper, the attention of speakers was almost entirely

absorbed in tuberculosis. Dr. Black Jones, M.O.H. Builth and Colwyn, stated that he did not institute legal proceedings against farmers under the Milk and Dairies Acts. His method was to teach, explain, and advise, and then to publish reports of the producers who had reached a proper standard. The results had been excellent. Dr. Nathan Raw described the success of compulsory pasteurization of milk in America, where, he thought, no doctor would in future have any experience of non-pulmonary tuberculosis in children. At all events, ten years of pasteurization of milk were stated to have eliminated these diseases in New York; it appears, however, that 6 per cent. of the Washington butter contains tubercle bacilli. Dr. W. G. Savage had apparently been prevented on previous occasions from replying to those who think that bovine tuberculosis confers immunity on children because the bovine bacillus is less virulent than the human. The evidence, said Dr. Savage, showed that the bovine bacillus was really the more virulent; its apparent innocuity was due to the fact that it was ingested—a different and more resistant path. At the afternoon session Mr. Neville Chamberlain recapitulated information for the benefit of a wider audience. The rest of the afternoon was devoted to a rather desultory discussion on various proposals for amending, defining, extending, and strengthening milk Acts and regulations. Many will be found to agree with Mr. Wilfred Buckley in condemning the deceptive title "Grade A" as applied to milk. Some amusement was caused by a representative who wondered how many of the audience had tried to milk a cow under really cleanly conditions. On the whole, we think that the National Clean Milk Society might wisely abandon its love of conferences, and devote its energies in two directions—first, to promoting knowledge among producers and distributors, and secondly, to striving by research to obtain answers to the many disputed questions connected with milk.

#### COST OF TUBERCULOSIS TREATMENT.

The Ministry of Health has issued a memorandum (122/T) showing in tabular form under various heads the cost per patient per week at certain residential institutions for the treatment of tuberculosis in England and Wales. The period under review is the year ended March 31st, 1926. The tables have been compiled on the same lines as in former years, and for purposes of comparison the corresponding figures for the previous two years have been inserted. The information thus set out is circulated in the hope that it may help the authorities concerned to decide whether in a given case the items of expenditure are on the lowest possible level compatible with efficiency. Analysis shows that in rather more than half the institutions for which comparative figures are available, the total cost per patient per week has increased, in some cases considerably, and that in a number of these the percentage of beds occupied to beds provided has diminished. Since full value for the expenditure incurred at a residential institution can only be obtained if all the beds are occupied, the Ministry asks local authorities to do their best to keep their beds filled to the greatest possible extent. Another matter to which attention is drawn is the proportion of staff to beds for patients; it appears to the Ministry that in some institutions "this question should continue to receive careful consideration."

#### ROYAL DENTAL HOSPITAL AND SCHOOL.

The staff and past and present students of the Royal Dental Hospital and School dined together at the Trocadero Restaurant on November 20th, under the chairmanship of Mr. W. H. Dolamore. Among the guests were several leading members of the dental profession in London and the provinces. The Chairman, in recalling the history of the school, said that the name of John Tomes was ever to be connected with its origin. He represented British dentistry in a sense which was scarcely true of any other one man, and he was the moving spirit in the foundation of the school. Speaking as a member of the Dental Board, Mr. Dolamore said that the Board's concern for professional progress was heartily supported by men who came on the *Register* under the Act of 1921 as by those who were there through qualification, and as a result of the efforts initiated

by the Board the movement for dental education was going forward, existing schools were being better equipped, and new schools would be opened. He looked forward to a large increase of dental students, notwithstanding a temporary decline due to passing causes. Mr. J. H. Badcock, past-president of the British Dental Association, whose name was associated with the toast of the school, spoke of the school as the mother of dental schools, with her children in every part of the British Empire. He also referred to the entrance of women into the profession; their excellent work already had fully justified the broadminded policy of the governors in admitting women to the hospital. Mr. Badcock gave some advice to those just entering dental practice—to join a defence union, to insure against accident and illness, and to become members of the British Dental Association. Further responses were made to the toast by one of the prizemen, Mr. M. Lewis, and by the dean of the school, Mr. H. Stobie, who gave an account of recent changes in the staff and other matters of domestic interest. Mr. A. L. Packham proposed the health of the guests, and the toast was responded to by Professor T. B. Johnston of Guy's, and the proceedings closed with compliments to the chairman, voiced by Mr. Norman G. Bennett, and warmly endorsed by the company.

## Scotland.

#### HENDERSON TRUST LECTURE.

A PUBLIC lecture under the William Ramsay Henderson Trust was delivered on November 12th by Dr. R. D. Clarkson, M.D., F.R.C.P.E., in the anatomy classroom of Edinburgh University. Dr. Hamilton C. Marr, Senior Commissioner of the General Board of Control, presided. The lecturer took as his subject "Some types of mental defectives," and said that in the popular mind three grades of mental deficiency were recognized. Over fifty years ago the lecturer's predecessor in the post of medical superintendent of the Royal Scottish National Institution at Larbert had suggested a classification under twelve types. The Mongolian type had been first distinguished in 1866 by Dr. Langdon-Down, who had been struck by the small broad head of these cases, which produced a Chinese cast of features. None of the tissues of these persons were normal, their ligaments were extraordinarily lax, so that many could sleep quite comfortably with the head between the feet, and as they grew older they never attained to the normal facility in the use of their limbs. There had been a belief that these were reversions to a forgotten ancestral type, and Dr. Crookshank had written a book, *The Mongol in our Midst*, in which it was made to seem probable that mankind had risen from at least three separate stems, so that there were affinities between the Mongol and the orang, between the negro races and the gorilla, and between the white races and the chimpanzee. This theory was negatived if the mental state of the Mongolian defectives were examined. They were placid, easily pleased, confiding, and gentle. They were incapable of forming abstract conceptions, and therefore never got any clear idea about their environment. They had a strong sense of rhythm, and were fond of music. A few of those who reached school age had very low intelligence quotients, and the majority were in the imbecile class. The highest of them might learn to read and write, but were very defective in arithmetic, and had to be cared for as children all their lives. It was fairly certain that if an ancestral branch of the human race had had such characteristics, it must have died out very soon and left no descendants. The simple primary defectives formed a less definite class and were regarded as degenerates. Stigmata of degeneracy were said to be very numerous, but every one of the physiological and physical stigmata, such as the deformed palate, malformed ear, and so on, might be found in quite normal people. The lecturer had grave doubts as to there being evidence of a degenerative tendency, although it was a fact that the bodies of idiots were seldom well formed. As in the bodily state of the simple primary cases there was no definite evidence of any one morbid

condition at work, so in their mental state every conceivable variation was found. It was quite common to find cases with sufficient intelligence to get on in life, but so defective in temperament that they failed. No test yet devised would detect these cases, and life was the only acid test for the certain detection of mental defect. Among the higher-grade defectives there were some whose defect was almost certainly the result of improper education. The growth of the mind was the result of innumerable reactions between the nervous system and its environment. If wrong reactions were formed into habits by constant encouragement, a child that might have passed as normal might revert into the defective class. The most important part of education was the building up in the years when the brain was growing fastest before the school life began. As yet there were not nearly enough special schools for children who were backward in development; further, it must be ensured that the good which was done to a child in such a school was not undone in the home or on the way home. No system of education, however, would bring the lowest grades up to normal, and these must continue to be a burden on the community. He considered, however, that all defectives should be prevented from having children; for, apart from the risk that their children might inherit mental defects, which was possibly exaggerated, it was certain that no child of a defective could have a fair chance of growing up to be a useful citizen, unless it was brought up by someone else. It was to be hoped that before long the community would make better provision for the defective and that diagnosis and treatment would be more successful than had been possible in the past.

#### CHEMISTRY AND BIOLOGY.

At a meeting of the Pharmaceutical Society, in the Society's Hall, Edinburgh, on November 19th, Professor J. Arthur Thomson, Professor of Natural History in the University of Aberdeen, gave the inaugural sessional address on "Chemistry in the service of biology." He spoke of the fundamental contributions to this subject to be found in the work of Lavoisier and Liebig. The former had introduced the idea of life as combustion, the latter had an equally important concept in regard to the circulation of matter. Important steps forward with far-reaching consequences had been made by Wöhler in the synthesis of urea, which had broken down the wall between organic and inorganic chemistry, and by Pasteur, whose chemical researches had appreciated the manifold activities of bacteria and foreseen the important role of fermentation in vital processes. One of the most important processes in the world was the synthesis that goes on in the green leaf under the action of light. There had been a long chain of discoveries in this subject from Priestley onwards. At the present day no one could do much in regard to the biology of the cell unless he was familiar with the properties of colloids. A recent instance of the invaluable services of chemistry to biology was found in the importance to muscular activity of glutathione, a substance discovered by Sir F. G. Hopkins. Services to embryology might be illustrated by Werber's experiments on the role of butyric acid in the production of monstrosities. The study of the nature and origin of organic pigments had been of great use in regard to the elucidation of biological problems of concealment, advertisement, or decoration. The modern work on the specificity of proteins had verified the old saying that all flesh was not the same flesh. It was possible that recent means of distinguishing by chemical tests between the blood of a male and a female animal might lead to discovery of the metabolic difference between the sexes. Indeed, all the descriptive sciences were bound to come more and more closely into co-operation in describing the nature and being of living things.

#### PERIODIC MEDICAL EXAMINATION.

An address on factory legislation was delivered on November 18th to the Unionist Workers' League by Dr. W. Robertson, medical officer of health for Edinburgh. Dealing with the Factories Bill of 1926, he said that there had been a tendency to do too much by legislation, and that the individual should take a share in the general levelling-up process that was going on. Among the most clamant

needs of the moment, however, was the establishment of a universal scheme for periodical medical examination of employees. Prevention was a watchword in medicine, and it should be continued to its logical conclusion by seeking to prevent sickness. If the victims of indigestion, anaemia, faulty teeth, defective vision, rheumatic pains, shortness of breath, headaches, and so on, were detected at the outset, the time and wages lost through sickness could be materially reduced. Under the National Health Insurance Act payment was made for the treatment of illness, but under a preventive scheme it was possible that sickness which might end in incapacity for work might be arrested. A plan of operations on a large scale naturally suggested the spending of money, but more payments from employer or employed could not be reasonably expected. It was natural, therefore, to turn to surplus funds belonging to the national health insurance scheme. If politicians were anxious to introduce more legislation, he suggested that the National Health Insurance Act should be so modified that a sickness prevention scheme might be established. In many instances large employers of labour had gone in advance of legislation by erecting factories replete with arrangements for the safeguarding of health. Housing schemes had also been established, welfare organizations set on foot, canteens provided, and various forms of outdoor recreation encouraged. The new Factories Bill had aimed at consolidating the Act of 1901 and subsequent enactments, but had very properly been held over for the present. The bill, when the time came for its introduction, would aim at making further advances in preventive work.

#### VITAL STATISTICS.

The return of the Registrar-General for Scotland for the third quarter of 1926 shows a birth rate of 20.1 per 1,000, a marriage rate of 6.8, and a death rate of 10.7. The number of births was 24,821. The corresponding rate is, with one exception, the lowest third quarterly Scottish birth rate yet recorded. In the counties the highest rate was in West Lothian and the lowest in Argyll. Of the larger burghs, Coatbridge stood highest with 25.7 and Edinburgh lowest with 18.4. The number of illegitimate births during the quarter, 1,749, is considerably below the average. The number of marriages during the quarter was 8,403. The rate for marriages is the lowest third quarterly rate in Scotland since 1917. The deaths registered during the third quarter were 12,865. The corresponding death rate is the lowest quarterly Scottish death rate on record, the nearest approach being 10.7 in the third quarters of 1922 and 1923. Among the counties the highest rate was in Caithness and the lowest in Peebles. Of the larger burghs, Kirkcaldy was highest with a rate of 12.5 and Dunfermline lowest with 7. The infantile mortality rate for Scotland during the quarter was 64 per 1,000 registered births, being the lowest third quarterly rate yet recorded, with the sole exception of the third quarter of 1923. The rates in the larger burghs ranged from 106 in Dundee to 30 in Dunfermline.

## Ireland.

#### ROYAL MEDICAL BENEVOLENT FUND SOCIETY.

THE eighty-fourth annual report of the central committee of the Royal Medical Benevolent Fund Society of Ireland states that the number of grants awarded in the year was eighty-five, as compared with eighty-six in the preceding year. That the income of the society from subscriptions has been increased even to a small degree during a year of marked financial stress is a matter for gratitude, and shows that in most of the counties the interest in the Fund is at least maintained. The income of the general fund from all sources was £2,390 11s. 10d., as compared with £2,097 1s. 6d. in the previous year. Receipts from dividends and interest increased by £66 13s. 3d. Subscriptions paid through the branches increased by £23 7s. 6d., while those paid through the central treasurer increased by £9 10s. 6d. The British Medical Association sent the handsome amount of £54 4s., collected during fourteen

months, January 1st, 1925, to February 28th, 1926; the amount collected during the year 1924 was £26 13s. Donations amounted to £31 10s., being life membership donations from Dr. Alfred R. Parsons, £21, and Dr. Thomas G. Stevens, £10 10s. The Irish Medical Association contributed £10 and the Dublin Clinical Club £5 5s. Two legacies were received. The late Dr. William Hennessy of Galbally left to the trustees of the Fund the sum of £100 for the purpose of providing an annuity of £5, or whatever that sum invested produced, for the benefit of widows or orphans of medical men, and the late Mrs. E. Thompson of Kingstown bequeathed £100 to the Fund; thanks were expressed to Dr. T. Hennessy, T.D., and to Mr. Herbert Dudgeon, the executors of these respective estates. These sums, together with a further sum derived from recovered income tax, have been invested in War Loan 5 per cent. stock, 1929-47, to round off the holding in that security at the even figure, £4,000. The Osborne fund being still in debt to the general fund, no grants have been charged against it; the debt has now been reduced to £4 9s. 2d. The committee points out that while receipts from dividends and interest during the past year amounted to £1,079 4s. 11d., the normal income from subscriptions was only £646 2s. 6d., and this, it was considered, afforded a rather remarkable contrast between the contributions of the dead and those of the living; while recognizing with gratitude the liberality of those who subscribe, it deprecates the fact that so many contribute nothing. Could the mass of the profession but realize how much the grants of the society mean to the recipients—comforts otherwise beyond their reach, clothes for themselves or for their children, and in some cases the very essentials of life itself—the committee believes that the number of supporters would materially increase. It asks those who know the society's work to canvass their colleagues who are not subscribers, so that the field of support may be extended and the financial stability of the Fund increased.

#### MEDICAL INSPECTION OF SCHOOL CHILDREN.

Dr. E. F. Stephenson, chief medical adviser to the Department of Local Government and Public Health in the Irish Free State, in a statement to the *Irish Independent*, announced that local authorities, in consultation with the newly appointed county medical officers of health, will prepare and submit draft schemes for school medical inspection for the approval of the Minister. The county medical officers of health when appointed will make preliminary surveys of the schools to ascertain the state of the general physique of the children and to estimate the standard attained in the different schools by children of approximately the same age. The school medical service should include the supervision of health, cleanliness, nutrition, and physical upbringing of each child, and should provide for periodical medical and dental inspections, with a view to preventing disease in the whole child population of school age. The regulations required general inspection of the children, special examinations of each child at specified age-periods, and careful investigation of defective children, followed by treatment. The inspections would be performed, where possible, in a room set apart for the purpose. It was intended to utilize the existing hospitals as treatment centres, and to employ the nurses engaged by district nursing associations, thus encouraging voluntary effort. In several cases special clinics, especially dental clinics, would be required. All the necessary institutions existed in Dublin, and the scheme there required practically no new machinery. The staff in each area would consist of the school medical officer, dentists, nurses, and, in large areas such as Dublin, an assistant medical officer. By co-ordinating with the scheme the nurses employed in maternity and child welfare work overlapping would be avoided and the health of the children would be supervised from birth to the time they left school. Dr. Stephenson added that there was no intention of rushing an elaborate and costly scheme on the country. No coercion would be employed, and a grant would be made to defray half the net cost of the approved schemes, payable in three instalments in the same way as the tuberculosis grant. Schemes

on these lines in Cork and Clonmel were developing satisfactorily. A general survey of Cork had shown the need for such a scheme. Of the children examined, 69.9 per cent. were found to have defective teeth, 19.5 per cent. defective sight, 6.8 per cent. nose and throat troubles, and 9.4 per cent. minor ailments. Uncleanliness was present in 11.8 per cent., and malnutrition in 8 per cent. All these children were being treated at appropriate centres. Treatment under the scheme would be limited to certain common ailments which permitted of more or less direct remedies—for example, defects of the eyes, ears, teeth, enlarged tonsils, adenoids, minor ailments, and uncleanliness. More serious cases, such as orthopaedic and spine cases, would be referred to the local authority.

## India.

[FROM OUR OWN CORRESPONDENT.]

#### CHOLERA IN MADRAS.

A SPECIAL study of the epidemiology of cholera is being made in Madras, and in his annual report for 1925 Major A. J. H. Russell, I.M.S., the director of public health for the Presidency, states that three papers on the subject are in the course of preparation. Colonel King, who was sanitary commissioner in Madras during part of the last decade of last century, asserted that where both the north-east and south-west monsoons affected a district its chief cholera season would follow its chief monsoon. This observation has been related to the conditions during a series of years, and it has proved substantially correct. In addition to this annual periodicity associated with the monsoons recent investigations have revealed a tendency for cholera epidemics to show violent exacerbations every seventh year. In 1918 nearly 123,000 deaths were recorded, and it was consequently anticipated that the incidence of cholera in 1925 would again be high. Preparations were therefore made, and although the forecast proved substantially accurate the mortality during 1925 was less by 7,000 than that of 1924, and only about one-third of that recorded in 1918. This indicates the value of the systematic preventive work in the infected districts, which was often carried on under considerable difficulties. In a special report submitted to the Government in 1872 the then sanitary commissioner, Dr. Cornish, concluded that cholera had no endemic centre in the Presidency of Madras, and that each fresh outbreak of the disease was due to waves of invasion from Bengal, either through the Bombay Presidency or the Central Provinces and Hyderabad. Recent investigations have, however, proved that these hypotheses were unsupported by facts, and that there are many endemic foci in the deltas of the large river basins in the Presidency. In each serious epidemic the first cases always appear in the same centres, and indisputable evidence exists to show that the infection spreads from these foci along the rivers and canals. The outbreaks arising in the delta areas of the Presidency are characterized by chronicity, whereas in other regions they are short and explosive. Certain districts are also in constant danger of invasion by cholera from neighbouring territories, such as Hyderabad and Pondicherry. Until recent years fairs and festivals played a prominent part in the dissemination of cholera, but since the introduction of the district health scheme considerable attention has been paid to the sanitary arrangements at these centres, and outbreaks of the disease are now exceptional. This prevention of cholera outbreaks associated with fairs and festivals necessitates also the taking of measures to safeguard the health of the pilgrims on the main routes leading to and from them. The importance of this, it is added, has not yet been sufficiently recognized, and severe cholera outbreaks have consequently resulted. Major Russell urges that the grants for rural water supplies made by the Government to local bodies should be so allocated as to improve and protect the sources of water lying along the main routes radiating from the festival centres. The efficacy of anti-cholera vaccines, both Haffkine's and

Besredka's, and the most suitable remedies for the early treatment of this disease, are also under examination. Of 2,570 persons in Coimbatore protected with anti-cholera vaccine only one died, and in this case death occurred within six hours after inoculation, so that infection must have occurred previously. In a series of 1,878 persons inoculated in Salem no deaths from cholera occurred. As regards treatment, recovery was recorded in 80 per cent. of 155 persons in all stages of the disease in another district. During the recent epidemics the district health staffs were substantially increased, and in some cases doubled. The chlorination of drinking-water supplies was extensively employed in preference to Hankinization with very satisfactory results.

#### MEDICAL DISPENSARIES IN ASSAM.

An account of the work of the dispensaries in Assam during the years 1923, 1924, and 1925 has been prepared by Colonel C. H. Bensley, I.M.S., superintendent of the civil hospitals in Assam. He reports that the number of hospitals and dispensaries at the end of the triennium was 237, and that on the average there are 2.2 to each 100,000 of the population, and 2.8 to every 1,000 square miles. There was a decrease in the number of patients treated, except in six districts, and this is attributed to the closing of some travelling dispensaries, the transfer of medical officers to kala-azar survey work, and the reduction of need for treatment in some localities owing to improvements in sanitation and the establishment of an increased number of private practitioners. In his statistical return it is shown that there was an increase in the treatment of malaria and diseases of the skin, eye, and respiratory system, while there was a decrease in cases of roundworm and rheumatic fever. Cholera also diminished, and the hope is expressed that this will be well controlled in future, since there are now two epidemic units at work, and anti-cholera inoculation is gaining in popularity; three more epidemic units are, however, required. During the three years special efforts were directed towards the control of epidemic diseases generally, and of kala-azar in particular. Campaigns and surveys were organized in districts, and new subcentres opened for treatment. There was an increase in the number of in-patients treated in the hospitals, and a decrease of out-patients. Liberal grants were made by the Government for the purchase of drugs and the general maintenance of dispensaries. While many local boards and municipalities are endeavouring to provide greater facilities for medical treatment by opening new dispensaries, inadequate provision is often made for those already in existence, very many being short of funds for the provision of medicine, equipment, and repairs, and hampered by large outstanding debts. Considerable relief has been derived from Government grants, but it is intimated that such assistance cannot be continued indefinitely. The public support of local board and municipal dispensaries is still very inadequate. Modern dispensary buildings and two cottage wards have been erected at Jorhat. A new ward has been added to the Lungleh hospital, and new dispensary buildings at Bijnai, Krishnai, and Saikhowa. Extensive repairs are in progress at various dispensary centres.

#### THE BURMA GOVERNMENT MEDICAL SCHOOL.

In the annual report of the working of the Burma Government Medical School in Rangoon for the year 1925-26 it is announced that it has been decided to admit no more students, and to allow the school to close down gradually. The educational facilities hitherto given by it will be afforded by Rangoon University. The number of students at the beginning of the year was 171, and 44 passed the final examination subsequently. Training for three months in practical midwifery was arranged for 45 students at the Government Maternity Hospital at Madras; this training is no longer available, and arrangements are now being made for the organization of the necessary courses at the Dufferin Maternity Hospital in Rangoon. Lieut.-Colonel J. Fuller-Good, superintendent of the school, gives an account of its satisfactory progress during the year; in all examinations a high percentage of successes was secured.

## Correspondence.

### REST IN ACUTE POLIOMYELITIS.

SIR,—Your very admirable article of November 20th (p. 947) on rest for acute poliomyelitis is most timely, and should be carefully noted by all practitioners. We are accustomed to look upon the first stage of the disease as extending from the onset until all pain has disappeared. If there is no pain or very transient pain it is wise to consider the first or acute stage as lasting six weeks, but so long as pain, or tenderness of the muscle, lasts we must regard it as an indication of active irritation of the central nervous system.

During this acute stage it is essential that the child be kept at rest. He should not be allowed to roll and twist in bed. The head, spine, and limbs should be held rigidly by a simple apparatus softly padded to ensure comfort. This Fabian policy may be trying to both doctor and patient, but it is certain that the child is in considerable danger from premature massage and electricity. In the presence of acute symptoms it is dangerous to stimulate the peripheral ends of nerves connected with haemorrhagic and inflamed centres. The room should be kept quiet and darkened, and nothing should be allowed likely to cause excitement. Not long ago, in consultation with distinguished physicians abroad, I saw a child in the acute phase of poliomyelitis. The physiotherapist, with all his apparatus, was already in the room in order to test the muscle reactions, while the child lay unprotected on the bed rolling and screaming in terror. Such an episode is a tragedy, and reflects grave discredit on our profession.

The other point upon which I would lay emphasis is that the paralysed groups of muscles, during the whole of the acute stage and until recovery has taken place, should be kept in the position of relaxation—that is, the limb should be kept extended if the quadriceps is paralysed; the foot inverted where the tibial group is affected; the ankle plantar-flexed where the calf muscles are paralysed; and on the same lines where other groups are involved. This is based on a fundamental principle which admits of no exception.

In conclusion, I wish to subscribe to all you say in regard to the closing of schools. With the knowledge we have of the infectious nature of the disease and its spread in the United States, there can be no justification for sending 500 boys all over the country, some of whom may well be carriers of disease.

I would recommend all who have the responsibility of advising school authorities to read the report of infantile paralysis in Vermont compiled by the late Professor Lovett of Harvard.—I am, etc.,

Liverpool, Nov. 23rd.

ROBERT JONES.

### EPIDEMIC POLIO-ENCEPHALOMYELITIS IN SCHOOLS.

SIR,—May I, with all respect, express a doubt that there will be general acceptance of the course of action advocated by Lord Dawson and Dr. James Collier—namely, that, in the presence of an epidemic of acute polio-encephalomyelitis, a school, already infected, should isolate itself and carry on. Let me enumerate the measures at the disposal of the school medical officer who is faced with such a problem.

As long as the epidemic remains entirely outside the school, he can attempt to turn the school into a self-contained and isolated community. In the case of a moderately large boarding school standing in its own grounds this can be done with very fair success. Parents, visiting teachers, and all outsiders can be prevented from entering the building, and the children, with the teaching and domestic staffs, can be confined to the grounds. Considerable difficulty may arise with the laundry, and still more will be met with in the matter of the domestic staff, and a much more reliable domestic than has yet been evolved will be needed to carry the plan through successfully over any length of time. This type of school is most favourably placed, but there are others. Mixed day and boarding schools cannot attempt the plan. Big public

schools with constituent houses are in the greatest difficulty. In the case of Uppingham, consisting of thirteen houses scattered in the town, the scheme of isolation is clearly and completely impossible, and the school cannot protect itself from the town. Nor can the town protect itself from the school if such a school becomes infected, and as the action of disbanding the school at Uppingham has been criticized as likely to spread the disease, it is well to point out that in such a case the public is going to be endangered whether the school is kept open or is closed.

But in the case of a school already attacked, what can a school medical officer do to ensure the safety of those in his charge? He can institute a throat and nose drill with the prescribed gargles and sprays. The results of such prophylaxis are hopeful, but no one could fairly say that it gives security. Apart from this, combined with general health measures, he can do nothing. His chief difficulty is that he cannot possibly isolate contacts, nor can he prevent a certain amount of crowding. What, then, is the position if the school is kept together? If the disease is spread by contact it means that with each fresh case a whole group of children is subjected to a fresh risk; if by carriers or dust, it means that the children are subjected to prolonged danger. In any case, had the children gone home, the risk to them would have disappeared once the initial period of danger was over. If it is reasonably certain that the disease is of epidemic type, there is no w . . . risk to the pupils as quickly as by

There seems a lack of thought in the criticism of this plan. If a carrier comes home and gives the disease to someone else, how is it worse than if he stays at school and infects a school-fellow? In their respective homes contacts can be isolated; in the community of a school they cannot. Further, I am afraid the psychology of parents is hardly allowed for. To ask them to regard this disease as in any way at all comparable with the infectious diseases they know is useless. They recognize no resemblance and, however many cases of permanent paralysis from it they see, and however many cases of children being found dead in bed they hear of, they will not be impressed with such resemblance. They do not look upon their school as a quarantine station, nor do they deem themselves fit to be responsible for the public health; they are simply anxious that their children should escape as quickly as possible and with the least risk. Nor is it reasonable to attribute their anxiety to ignorance, for it is those who know about the disease who are the most apprehensive. Let me relate my experience.

In the late Broadstairs epidemic Dr. Hugh Raven asked me down to consult with him about two schools under his care, neither of which had been infected. A letter was written in which we were able to say that in both cases the schools had not been exposed to any danger for a time already longer than the usual incubation period, and that their position was by then practically safe. Before this report could reach the parents the news of the epidemic was in the press. In one school there were three children from the "Harley Street area." On my return to London the next morning the parents of these three children were the very first to be at me, and I had seen them all within an hour. All of them had settled to take their children home that very day, and only what I was able to tell them kept them from doing so. Their action guided many other parents, and I believe no child was removed after that date. But my point is that those who were most anxious were the very ones who knew the disease; and I must own that to those who asked, should I prove wrong and a case occur in the school, ought they then to remove their children, I could only answer "Certainly."—I am, etc.,

London, W., Nov. 20th.

REGINALD MILLER.

In response to inquiries for information we have received the following letters:

SIR,—I am glad to say that now, eleven days after the boys returned home from Uppingham, only one case of poliomyelitis has been reported to us. It is rather a coincidence that this boy has a younger brother at home who was removed from Broadstairs. The total number of

cases in Oakham urban and rural districts was fourteen; in Uppingham two cases—the Uppingham School cases. There is very little communication between the two sides of the county. The Uppingham School authorities are well aware of the gravity of breaking up during term—this is the only occasion—but the risk to boys of an epidemic was considered sufficient to justify it. Events have proved this, apart from hundreds of letters from grateful parents, many of them medical men. I do not think it is necessary to deal with the letter of Lord Dawson and Dr. Collier in the *Times*. From letters received by me the profession seem to understand the position.

Now that epidemic poliomyelitis has started in England we are likely to have another outbreak next year. I hope the medical officers of schools will meet to discuss the matter, and formulate a scheme, if possible, to deal with a disease of which so little is known.—I am, etc.,

WILLIAM DUNN, M.B.,  
Medical Officer, Uppingham  
School.

November 23rd.

SIR,—The following are the facts with regard to poliomyelitis at Oakham.

We had three cases in September, one a lad of 15, who died within a week of the appearance of symptoms, the second a local policeman of 28, and the third a girl of 9. The last patient contracted the illness at Leicester, and was sent home to Oakham after the acute symptoms had disappeared. The two latter cases were treated at the local cottage hospital, and were later transferred to the Hospital for Paralysis, Maida Vale.

There was a fourth case, a child, in October, and a fifth, also a child, in November. This last was first seen on November 2nd; since then we have had no fresh cases. There have been no cases in the Oakham school.

I have had two cases in two neighbouring villages, and I understand Dr. Skipworth of Market Overton, the adjoining practice, has had five or six cases.

The extraordinary and inaccurate statements in the press with regard to the epidemic have had the effect of alarming the people generally, and the parents of boys at school particularly. If a calm, authoritative statement could be made by the Ministry of Health with regard to this epidemic it would materially help to counteract this.—I am, etc.,

Oakham, Rutlandshire, Nov 22nd.

T. CLAPPERTON.

We are indebted to Dr. J. E. O'Connor, M.O.H. for Leicestershire and Rutland Combined District, for the following information concerning the notifications of poliomyelitis in the district. The first notifications for the Leicestershire districts were made during the week ending August 21st, and numbered 4; the notifications for the ten weeks August 28th to October 30th were as follows: 5, 1, 6, 14, 4, 4, 2, 3, 2, 4—the total for the eleven weeks being 49. The cases occurred in a great many parishes, and in no instance was there more than one case per house; most of the cases were treated at home. The notifications for the county of Rutland numbered 17; they occurred as follows: 2 in the week ending October 9th, 5 in that ending October 23rd, 6 in the following week, 2 in the week ending November 6th, and 2 (in Uppingham School) in that ending November 13th. In the Oakham rural district, in which 12 cases were notified, there were 3 in one house and 2 in another.

Dr. O'Connor adds: It will be observed that no case has been notified in any of my Leicestershire districts during the present month. In Rutland districts, where 4 out of 17 cases proved fatal, the disease has been relatively far more prevalent, as their total population is under 16,000. It is now eleven days since the onset of the last case.

#### THE CANCER VIRUS.

SIR,—Dr. Gye in his article on the cancer virus in your issue of November 13th apparently refers to my suggested interpretation of his work—wherein he remarks on "the extremes to which men will go to explain away a fact which runs counter to a strongly held opinion." He also says, "such views, I hope, need no reply."

Dr. Gye must remember we are dealing with an exceptional tumour, and the case perhaps demands an exceptional explanation. At any rate it is neither helpful nor logical to dismiss the view with the hope that it need not be answered. I maintain that the view expressed in my letter to the *BRITISH MEDICAL JOURNAL* of January 30th last is a possible interpretation of the facts, and well within the scope of scientific conception.

I would therefore again ask the question in the hope that it will be answered, "Has Dr. Gye in his experiments merely broken up the malignant cell into cytoplasm and filterable fragments of nucleoplasm, and then reunited them in another host?" For the essential and characteristic property of nucleoplasm is its power of auto-synthesis if placed in a suitable pabulum, thus reconstituting itself as the true genetic cell.—I am, etc.,

FRANK B. SKERRETT, M.B., B.Sc.Lond.

Town Hall, West Ham, Nov. 20th.

#### SURGERY IN GENERAL PRACTICE.

SIR.—It seems to me a most unfortunate circumstance that Sir James Berry, at the Royal Society of Medicine's dinner, should have considered it a public duty to reflect prejudicially upon the present-day tendency of general practitioners to take up surgery in its larger aspects.

Whether this be the truth or not is beside the point, unless he can also indicate the remedy. His only suggestion in this direction is that the public should exercise care in the selection of a surgeon!

The chief result of his outspoken remarks has been a host of articles, sub-leaders, and interviews in the public press, nearly all of which show complete misunderstanding of what was, presumably, Sir James's real intention—which I take to be the prevention of general practitioners undertaking big operations more or less promiscuously, without the necessary training, knowledge, and skill. I think the vast majority of the profession will endorse this view.

On the other hand, what do the public, as evidenced by the journalistic efforts it has evoked, know of the distinction between specialists, general surgeons, house-surgeons, honorary medical officers of provincial hospitals, and general practitioners?

It is certainly true that the war led to a great increase in the amount of surgery done by general practitioners by reason of the fact that an army of pure surgeons took an active part in France and elsewhere; and it became a necessity for patients, both hospital and private, to put themselves in the hands of their own doctors or other local practitioners recommended by them. For the first time patients realized that much good work and difficult operations might be performed by local men, and at a much reduced fee. This state of things has continued more or less to this day.

Then, when the war was over, numbers of R.A.M.C. men, accustomed to performing many and varied operations while in the army, so soon as they started in practice as partners or otherwise naturally did all they could to continue to get as much surgery as possible. The able man, in either of these categories, if honest, would only undertake such things as he felt competent to do; cases beyond his ken, and special work, he would advise being given to a "special" surgeon.

It is useless to make sweeping remarks about general practitioners—they vary in quality and degree as men may in any other profession, or even as surgeons do themselves, and, as a matter of fact, outside the big cities they are all general practitioners who staff the hundreds of provincial hospitals.

If general practitioners are to be prevented from doing big surgery, then many thousands of urgent abdominal cases and tens of thousands of sub-urgent cases would have to be sent to London and other large centres. And with what result?—no beds to hold them, or not enough surgeons to operate.

No! Common sense must be introduced with the subject. Who is to decide what or which is a major operation—what is to be done if an apparently small beginning results in a great finding? Is the operator to wait until a bigger man arrives—too late, from the patient's point of view?

In my opinion the big men are themselves to blame to a great extent. Fees are too often grossly beyond the actual value of the operation, and the public know that many local men are competent and willing to do the same thing with an equally good result for a very much smaller fee, and they trust their medical adviser to recommend a special man for the job if they think it necessary. It seems so unfair that one fee should be ten guineas and another two hundred—the increase in relative value is fictitious.

I am quite sure the swing of the pendulum towards too frequent operation by general practitioners not on hospital staffs will soon begin its return journey and normal will gradually be attained; but I am equally sure that each man should endeavour to make and keep himself as efficient as possible, and I am also equally sure that any breach in the good relations between general practitioners and consultants—who, if not always complimentary, are complementary to one another—can only militate against the best interests of the public and the profession.

That is why I think all such public utterances as those made by Sir James Berry are so harmful, and one can only hope they will not be repeated. I beg to enclose my card.—I am, etc.,

November 22nd.

A GENERAL PRACTITIONER.

SIR.—May I, as a general practitioner, crave space to express my indignation (shared, I feel sure, by my brethren) on reading the views aired by Sir Arbuthnot Lane, and adumbrated by Sir James Berry on November 18th?

I write to you, Sir, because, generally speaking, we general practitioners do not choose to figure largely in the lay press. We feel that the representatives of the public papers have access to our journals, and that it is perhaps a little beneath the dignity of a general practitioner to depreciate publicly the work of his colleagues.

Sir James Berry is quoted as saying, "Those of us who are behind the scenes in the surgical world see only too much of what is going on." May I add that those of us who are behind the scenes in general practice see a good deal too? And some of our most difficult cases are those who, in Sir James Berry's cryptic words, "wanted an operation and took care who did it."

Sir Arbuthnot Lane sums up the situation by saying that people get exactly what they pay for. Herein he does his own great profession and a vast body of conscientious practitioners a grave wrong. He should have added that this was strictly his own experience. There are those amongst us who do not excise our pound of flesh from every patient; it would be a sad and bad day for many of our needy patients if we did. "There is only one remedy" [says Sir Arbuthnot Lane]; "we must educate the coming generations of doctors." Perhaps he may be induced to assist at this great and onerous task himself when he has completed his education of the public.—I am, etc.,

EUGENE H. COYNE, M.C., M.Sc., M.B.

London, S.W.2, Nov. 20th.

#### SANATORIUM TREATMENT.

SIR,—In answer to Dr. Weatherhead's kind criticisms of my remarks in a recent number of the *JOURNAL*, I may say that twenty-five years ago I analysed the histories of about 300 patients who had been inmates of the Brompton Hospital, most of whom were at that time well advanced cases of pulmonary tuberculosis, and most of them had been infectious for years. I found that the initial symptom in 19 per cent. was haemoptysis, and that the time between the haemoptysis and admission to hospital averaged three years. In addition, in 20 per cent. of the cases the initial symptom was pleurisy, and the time between the pleurisy and admission to hospital averaged four and a half years.

It would thus appear possible to admit to sanatoriums 40 per cent. of cases, the majority of them curable, without filling the sanatoriums with doubtful material. Ordinary methods of differentiating cases of haemoptysis and pleurisy not due to tuberculosis would be used; where no other cause for the disease could be found, then the cases should be treated as tuberculous without delay. It should be explained to these patients that if they recovered they would

be in no danger of espionage from the sanitary service, thus placing them on a level, as regards liberty, with patients suffering from venereal disease. This would protect the public from mixing for years with infectious cases, often in complete ignorance of their condition. Most of these cases would either never become infectious or would lose their infection under treatment.

The treatment of such cases would occupy only a small fraction of the time taken now in keeping alive more or less permanently in our midst a large number of infectious patients. By the method I propose we should be restoring patients to health and preventing infection all along the line, we should be able to spend much less on hospitals for advanced cases, and colonies and tuberculosis villages would be unnecessary.

The eradication of this disease is largely in the hands of the general practitioner, whose confidence requires strengthening; a large proportion of the cases he sends must do well, and if this is to happen it is probable that a great deal more rest will have to be prescribed in sanatoriums that at present.

We must be careful not to add to the disabilities of patients who are willing to be treated; remembering that at the present time it is not the infectious who are penalized, but only those who have been willing to undergo treatment and thus render themselves innocuous. —I am, etc.,

Ayrshire Sanatorium, New Cumnock,  
Nov. 14th.

EDWARD E. PRIST.

SIR,—I read with interest your review in the *BRITISH MEDICAL JOURNAL* (August 28th, 1926, p. 397) of a memoir by Dr. Stocks and Mr. N. Karn, dealing with the results of treatment in the Belfast Municipal Sanatorium.

The validity of Dr. Stocks's conclusions has been questioned on account of several factors by your correspondents, who have, however, confined their criticisms to the material on which the investigation is based. Even if one assumes that the figures on which the authors base their calculations are quite incomplete and grossly inaccurate, that does not explain the inferior progress of the sanatorium-treated cases. Errors in diagnosis and in recording clinical facts would roughly cancel out in the respective groups compared by the authors.

I should like to point out an error in the joint authors' calculations which goes far to explain the astonishing conclusions reached by this inquiry. Dr. Stocks and Mr. Karn have compared the progress "of 170 incipient cases who were treated during some part of the period (not less than fourteen days) at sanatorium and during the rest of the time at dispensaries, and the progress of 499 cases who received only dispensary or domiciliary treatment" (p. 414, lines 14-17). From this one learns that only 25 per cent. of incipient cases had sanatorium treatment at any period of their illness, and it is important to note that the anatomical classification is based on the physical signs *when the patient is first examined*.

"The anatomical grouping was almost invariably entered on the schedule by the tuberculosis officer when the initial complete examination was made: where this was not done it was usually possible to assign the case to its proper group from a careful examination of the lung chart and report of examination of the chest: in only a small proportion of cases was there insufficient information to enable an anatomical classification to be made." (Page 410, lines 15-19.)

The amount of systemic disturbance in these incipient cases is also estimated *when the case is first observed*.

"To test this possibility each case was classified into one of three groups, S<sub>1</sub>, S<sub>2</sub>, S<sub>3</sub>, according to the severity of symptoms when the case was first observed, as defined in Section 3." (Page 434, lines 26-28.)

The authors admit (p. 436) that the proportion of cases with little or no systemic disturbance is smaller in the sanatorium-treated group, and make a correction accordingly, but they have ignored a much greater fallacy. They appear to have forgotten that the average time interval from first visit to dispensary (that is, the

date of classification) to admission to sanatorium is 279 days for incipient male cases and 339 days for incipient female cases (p. 413). We are entitled to speculate as to the relative progress of the sanatorium-treated and the non-sanatorium-treated groups during this considerable space of time. Is it not reasonable to assume that those cases which deteriorated materially during the first six to twelve months of dispensary attendance declared their willingness to enter the sanatorium, especially as the period under consideration (May, 1914, to July, 1917) was one of good employment and high wages?

It appears, then, that of 669 cases of incipient pulmonary tuberculosis in Belfast, 170 had sanatorium treatment after a considerable period of observation. These cases are compared with 499 incipient cases who did not have sanatorium treatment after the same period of observation. Broadly speaking, this is to compare the sick with the comparatively healthy, and it is not astonishing that those who felt well enough to carry on outside the sanatorium should show a higher degree of ultimate progress. May I illustrate the point by an example? On January 1st, 1915, two patients present themselves for examination at the tuberculosis dispensary. Both have suspicious symptoms and physical signs: they are classified L<sub>1</sub>, S<sub>1</sub>, and advised to attend again. The first patient feels better after a rest, resumes work, and soon ceases to attend the dispensary. The second patient, who has active pulmonary tubercle, becomes worse, perhaps has a haemorrhage, an acute pleurisy, or a rapid loss of weight. Then, after six to twelve months' delay, the second patient consents to "try the sanatorium." By this time the physical signs may be advanced, and the symptoms of tuberculous toxæmia may be severe. Nevertheless, according to the classification of Dr. Stocks and Mr. N. Karn, this patient is an incipient case with slight or no systemic disturbance.

The real value of sanatorium treatment, about which I express here no opinion, will never be assessed by such faulty methods of reasoning as are used by the joint authors of this memoir.—I am, etc.,

Medical Superintendent, Forster Green  
Hospital.

Fortbreda, Belfast, Nov. 15th.

### A STRANGE EPIDEMIC:

DIARRHOEA: LOCAL ASPHYXIA: RASH.

SIR,—The following are the details of a somewhat perplexing epidemic of diarrhoea which, at the moment of writing, is rife at Sunshine House, Chorley Wood, one of the resident homes for blind babies supported by the National Institute for the Blind. If any readers of the *BRITISH MEDICAL JOURNAL* have met with any similar cases or can throw any light on the obscure etiology of this outbreak we shall feel greatly obliged if they will communicate with us.

The cases have occurred almost simultaneously among the members of the nursing staff, and among the children; only one domestic, the laundry-maid, has been attacked. Although the symptoms among the adults and among the children have many features in common, there is this distinction, that only the children have suffered from the skin condition presently to be described. But in spite of this difference it is difficult to believe otherwise than that all the cases are due to one common cause.

The symptoms are as follows: the attack commences with a feeling of intense tiredness, followed in twenty-four hours by acute pain in the epigastric region with diarrhoea, and in some cases with sickness. In the adult cases complaints were made of frontal headache with a queer feeling of fuzziness in the head. Intense drowsiness was also complained of, and in one or two cases there were attacks of faintness.

The young children do not appear to be in any great discomfort, but they are distinctly apathetic and listless. One baby, a few months old, showed symptoms of cerebral or meningeal irritation. In none of the cases has there been any rise of temperature, the pulse has been invariably slow, and the blood pressure low. Recovery takes place at the end of three or four days

<sup>1</sup> The references are to the original memoir, *Annals of Eugenics*, Vol. I, Parts 3 and 4, April, 1926.

The real peculiarity of this epidemic is that among the children, in addition to the symptoms already described, there is a condition of the toes and feet which looks like local asphyxia almost amounting to gangrene, the parts affected appear as if they were frost-bitten, and there are localized spots of erythema which look as if they would ultimately vesicate, but in no instance has this actually taken place. The spots range from the size of a small pea to that of a large bean; they are round or oval in shape. They are distributed over the toes, the soles; and the dorsum of the foot, and none have been noticed in any other situation. They are painless, and not tender to pressure. In the end they become dry and scaly and appear something like erythema iris or ringworm.

The epidemic started on November 13th, and has continued intermittently up to the present time. Out of 24 children 11 have been attacked, and out of 10 nurses 8 have fallen victims. Only one of the domestic staff has been attacked, and she slept in the nurses' quarters and had her meals apart from the rest of the other servants.

The etiology of this epidemic is complicated by the fact that during its course there was an overflow from an unsuspected cesspit which flooded the cellars and filled the whole establishment with a foul-smelling effluvia.

Although in most of its features the epidemic is more like one of infective origin, the absence of all pyrexia militates against this diagnosis. Its intermittent character is contrary to the diagnosis of food poisoning or botulism, and poisoning by sewer gas does not seem altogether probable.—We are, etc.,

Consulting Physician for the Sun-  
shine Homes for Blind Babies.

November 21st.

#### CLOTHING AND CATARRHS.

SIR,—Dr. Leonard Williams accuses me of an act of crude discourtesy in writing so strongly as I did "over a legitimate difference of opinion as to the respiratory function of the skin." If this were the case I should indeed feel ashamed to have written my letter, but, as he evades the greater part of my argument, I hope I may be allowed to try and refute his accusation.

I made three points against Dr. Williams's hypothesis. The first and least important was that the respiratory function of the skin is almost negligible. The second was that, even supposing that this function is important and were abolished, leading to increased respiration by the lungs, there is no sort of reason to suppose that this would lower their resistance to bacteria. Increased respiration for most people is surely healthy. My third point was that in so far as warm clothing acts on the respiratory function of the skin it tends to increase it.

To the first point alone Dr. Williams replies to the effect that while such is the usual teaching, he differs, as he might, on such a question as the function of the appendix. To this I rejoin that here is not a doubtful question in medicine, but an established fact in the science of physiology, established by direct experiment, and only to be refuted by such. But, even allowing that Dr. Williams is right by some intuitive process and the physiologists are wrong, and that by a further intuition he is correct in supposing that they have made another mistake in saying that hyperaemia and sweating increase the skin's respiration, and that he elects so to dispose of my third argument, he has still to answer my second, which combats the very essence of his hypothesis.

It was the cumulative effect of these three points which really made me think that it was more charitable to assume that Dr. Williams did not advance his idea seriously, but thought it was good enough to use to rub in some doubtless excellent hygienic precepts in the same way as most of us may be led into making dogmatic statements to patients for their good.

That was my excuse for the tone which I adopted in my first letter. If Dr. Williams does now intend to maintain his hypothesis in a scientific journal, I can only say that

I have here given fully my reasons for opposing it, and that while I regret the misapprehension which gave rise to the tone of my first letter, I also regret that Dr. Williams did not emulate the writers therein referred to, but chose the medium of a popular article in the lay press to exploit such a remarkable contribution to the pathology of catarrhs.—I am, etc.,

A. R. JORDAN.

Dover, Nov. 21st.

SIR,—In view of the fact that the epidermis consists of four strata (each composed of several layers), that the surface is cornified and covered by a film of grease, and that the whole is non-vascular, respiration through the skin would appear, if not impossible, certainly negligible.

Dr. Leonard Williams asserts it does take place. Will he please inform the profession as to the nature of his experiments in proof of his contention.—I am, etc.,

J. F. P. GALLAGHER.

Bournemouth, Nov. 22nd.

#### Obituary.

##### THE LATE DR. FRANCIS WARNER.

DR. FRANCIS WARNER, of whom an obituary notice was published on November 6th (p. 857), was a pioneer in the investigation of mental abnormality from the physical standpoint. The greater part of his work was connected with the study of children, and led to such important practical sequels as the provision of special schools for blind, deaf, and defective children, and the eventual adoption of a more hopeful and scientific attitude to cerebral disorders. In the course of a paper before the Section of Psychology at the Glasgow Meeting in 1888 he enumerated the physical signs which, in his opinion, pointed to slight degrees of mental impairment, and he suggested that an investigation should be made on a large scale to determine the degree of mental health of children in primary schools. A committee was appointed for this purpose by the Council of the British Medical Association, and became part of a large organization; it carried on its work until 1897, assisted by grants from the Association, amounting in all to £653. The first report of the committee appeared in 1889; considerable difficulty had been encountered in obtaining permission for the examination of children in certain primary schools, and a recommendation was then made that a scientific investigation on a larger scale should be instituted by the Government. In the course of the nine years during which the committee was at work Dr. Warner examined systematically 100,000 children, and statistical reports were issued from time to time. In 1890 an account of the examination of 50,000 children, seen in 106 schools in London, was published in the report of the Commissioner of Education for the United States, and a full report was published later by the British Medical Association; with recommendations as to education and training, several of which were adopted in subsequent legislation. Considerable differences in the development of children were found in certain localities and nationalities. Various other reports were published later in the *BRITISH MEDICAL JOURNAL* and, as already mentioned, in the *Journal of the Royal Statistical Society*. Dr. Warner became, naturally, a recognized authority on this subject, and took an active share in the work of the Royal Commission on Blind, Dumb, and Defective Children in 1889, the Departmental Committee of the Local Government Board on the Feeble-Minded in 1896, and the Committee of the Home Office on Reformatory Schools in the same year. Two years later he was associated with a departmental committee of the Educational Department, which investigated problems concerning defective and epileptic children, and in 1903 was a member of the Royal Commission of Physical Training in Scotland. His main conclusion that brain conditions, including mental action, could be interpreted in terms of neural function, and be considered physiologically and pathologically, was finally established, and considerable light was thrown by him on the problems of infant mortality and feeble health in childhood.

Mr. ROBERT HARRY LUCAS died on November 6th at his residence in Bury St. Edmunds, aged 81. He was the third son of Dr. Thomas Lucas of Burwell, Cambridgeshire, and received his medical education at the Middlesex Hospital, where, after obtaining the diplomas L.S.A. and M.R.C.S. in 1869, he held the posts of house-surgeon and resident medical officer for several years. In 1879 he began private practice in Bury St. Edmunds as a partner of the late Dr. McNab, whom he afterwards succeeded. He was a member of the honorary staff of the West Suffolk General Hospital, and took a leading part in the organization and extension of its surgical department. On his retirement from active practice in 1909 Mr. Lucas was appointed consulting surgeon. For many years he held a commission as surgeon captain in the Loyal Suffolk Hussars; during the late war he was attached to the Suffolk Depot Military Hospital, and was a member of the Military Service Medical Board. He was a justice of the peace for Suffolk and a regular attendant at the Thingoe Petty Sessions. Mr. Lucas gave active support to the British Medical Association over a period of many years, and was a member of the East Anglian Branch Council from 1899 to 1903. He was chairman of the West Suffolk Division in 1904, and a member of the Representative Body in 1912 and 1913. He leaves a widow and one son, who is in the medical profession.

Dr. WILLIAM FRANK MORGAN, who died suddenly on November 3rd at Wilton, near Salisbury, at the age of 38, received his medical education at the London Hospital, and obtained the diplomas M.R.C.S., L.R.C.P. in 1913. After assisting in a practice near Leeds, he obtained a commission in the R.A.M.C. at the beginning of the war, and spent most of his service in the front line, retiring after the armistice with the rank of major. Since 1920 he had been in partnership with Dr. A. W. K. Straton at Wilton, where he became very popular by reason of the soundness of his work and the quiet kindness of his nature. He was a member of the British Medical Association and a Fellow of the Royal Institute of Public Health.

## Universities and Colleges.

### ROYAL COLLEGE OF SURGEONS OF ENGLAND.

#### ANNUAL MEETING OF FELLOWS AND MEMBERS.

THE annual meeting of Fellows and Members of the Royal College of Surgeons was held on November 18th, with the President (Sir BERKELEY MOYNIHAN, Bt.) in the chair. About sixty were present.

THE PRESIDENT said that the Supplemental Charter as prayed by the College had been granted. It was approved by the King in Council on July 26th, signed and sealed on August 16th, and received by the College on August 24th. The charter itself made no alteration in the by-laws, but it gave the Council power to do so. These had to undergo a rather tedious process before coming into force, but a process deliberately made slow in order that the fullest consideration might be given to any changes. These changes must be considered at three meetings of the Council, they must then be submitted to the Home Secretary, be examined and allowed by certain Law Officers of the Crown, and finally approved by the King in Council. Alterations in certain sections of the by-laws, required to carry out the provisions of the new charter, had already passed through certain of these stages, and it was hoped that the new by-laws, if they received no challenge from the Law Officers, would come into force early in the New Year. Turning to other matters in the annual report of the Council, Sir Berkeley Moynihan said that the award to Dr. Gye of the Walker Prize would be approved by the whole profession. (Applause.) The Cartwright Prize had been awarded to Dr. Sim Wallace, and the Lister Medal to a great friend of his own, Professor von Eiselsberg of Vienna. The College had been approached by the Canadian Medical Association, which desired facilities for Canadian medical practitioners to obtain, by post-graduate study and examination, the Fellowship of the College. Certain quite informal discussions had also taken place between the Council and representatives of Australia. He need not enter into this matter at the moment; the only thing necessary to say was that every member of the profession would desire the Council to do whatever was in its power to bring about a closer relationship between the Dominions and the College. (Applause.) The last year had been very satisfactory in respect to two matters. The College last year issued 768 new diplomas of membership. This figure was second only to the highest in previous years. Clearly the diploma

of membership, despite certain disadvantages which apparently in the minds of some members still attached to it—(laughter)—was a diploma very highly valued. So far as the finance of the College was concerned, the receipts had only on one previous occasion been larger than they were during the last College year.

In reply to Mr. C. E. WALLIS, who asked what was the cost of obtaining the Supplemental Charter, the SECRETARY said that the fees paid to the Government authorities were £102; the total cost, including the official fees, was somewhere about £250. Dr. FINUCANE remarked that out of the total revenue of the College of £43,630, no less a sum than £24,803 was derived from fees connected with Membership examinations. He thought that the expenditure on examinations (£12,962), representing one-half the expenditure of the Conjoint Examining Board, was unduly high. Dr. C. W. BROOK drew attention to the examiners' fees in the third examination (£7,228), which he thought an excessive figure.

Dr. H. WANSEY BAYLY then moved the usual resolution:

That this thirty-eighth annual meeting of Fellows and Members again affirms the desirability of admitting Members to direct representation upon the Council of the College, and respectfully requests the Council to take a postal vote of Fellows and Members on the general principle as set out in this resolution.

He urged that the system of government at present existing in the College was archaic and not democratic. The College was governed by a Council composed entirely of, and elected by, Fellows, while nearly 90 per cent. of the College—the Members—had neither voice nor vote in its affairs. Before 1843 the governing body was composed of Members only. The Supplemental Charter granting similar rights to women Fellows, Members, and Licentiatees as were now enjoyed by men involved an alteration in the by-laws which had not yet come into effect, and he regretted that the procedure could not have been accelerated to permit women Fellows and Members to exercise their new rights at that meeting. To make the Council representative it should include at least one woman Fellow and one woman Member. Although many Fellows were now engaged in general practice the majority were still consulting or operating surgeons attached to the staffs of hospitals, and it might be argued that general practitioners, whose work was in the homes of the people, were in closer touch with the realities, humanities, and difficulties of the great work of the profession than were consulting or operating surgeons. Members of the College had that wholesome dislike of patronage common to all free citizens, and in pressing for some representation for themselves on the Council they were demanding a right and not asking a favour. He added that the Society of Members had on several occasions undertaken a postal vote on this question, and on each occasion the replies of Members, and of Fellows also, had shown a majority in favour of the inclusion of Members on the Council.

Dr. REDMOND ROSE seconded the resolution, and took occasion to thank the late President and Council for the courtesy shown to the deputation from the Society of Members when it appeared before them to bring forward the case for the direct representation of Members. The Council did not grant the request of the society, but gave it very careful consideration, not only when the deputation was received, but at two or three subsequent meetings held specially to consider the request. He and two other Members then prepared a counter-petition to His Majesty in Council. This went through various stages, and was passed back to the Council of the College for observations, and the matter got no further, the Council considering that controversial questions were being introduced which would imperil the obtaining of the charter. He demurred to the word "controversial," though it was, of course, difficult to get unanimity in the profession on any question really worth considering. With regard to the postal vote, he felt strongly that the granting of representation was a matter of abstract justice, and it was not usual in proposing any extension of franchise to invite the people concerned to say whether they wished to be enfranchised or not. But if the Council really thought this was an exceptional case in which the opinions of Members and Fellows generally should be sought, the Council itself was the proper body to undertake the canvass, and he and his friends had no fear whatever of what the result of any postal vote would be. He added that although the Council had given an unfavourable reply to the deputation, a happier atmosphere had been created as a result of recent events. A new era in the negotiations between Members and the Council had been inaugurated, and he hoped that the Council of its own volition would see its way to concede this request.

Mr. ERNEST WARE created some amusement by paraphrasing a passage in the President's recent oration before the Medical Society of London, in which he had pleaded for greater union between the surgeon and the physician: "How much more rapid our progress would have been, and how much more fertile our labours, what waste of time and effort would have been spared, if instead of each living inside his own impenetrable ring-fence, the Fellow and the Member had met on common ground in the interests of the College." Dr. C. W. BROOK, speaking as a parliamentary candidate, said that the time was approaching for a change of Government, and when this question came forward the whole matter of registration and qualification would be involved; among other

things the organization of the College would come under review, and drastic measures might be taken in the House of Commons.

Mr. Howard Strarford, while of opinion that the majority of members of the Council should be Fellows, thought it would be all to the good if two or three Members were included. The Council and the College would greatly benefit from the co-operation on the Council of a small number of well informed general practitioners. Dr. L. B. Ward said that the limit of constitutional methods of protest had now been reached, and if nothing came of the present resolution the Society of Members would reduce itself to a farce by proposing further annual resolutions. It would be very regrettable to have civil war in the College, or the boycott of a section by the majority, yet this might happen if the Council persisted in its narrow-minded view of the functions of government. Dr. F. W. COLLINGWOOD and Mr. R. GILLBARD also supported the resolution, the latter making a personal appeal to the new President to seize this rare opportunity of breaking down exclusiveness and generating peace.

The resolution was then put to the meeting and carried with one dissentient.

#### UNIVERSITY OF LONDON.

A MEETING of the Senate was held on November 17th, with the Vice-Chancellor (Sir William Beveridge) in the chair.

Regulations were adopted for the recently established academic Diploma in Anthropology.

The degree of D.Sc. in Physiology was conferred on D. T. Harris, an internal student of University College, for a thesis entitled, "Biological action of light."

Sir Holburt Waring, M.S., F.R.C.S., has been elected chairman of the Brown Animal Sanatory Institution Committee for 1926-27.

#### Semon Lecture.

The Semon Lecture, 1926, as already announced, will be given this year by Dr. A. Brown Kelly of Glasgow on Thursday, December 2nd, at 5 o'clock, at the house of the Royal Society of Medicine (1, Wimpole Street, W.). The subject of the lecture is "Nervous affections of the oesophagus," and the chair will be taken by Dr. Andrew Wylie, President of the Laryngological Section of the Society. Reception and tea at 4.30 p.m.

#### SOCIETY OF APOTHECARIES OF LONDON.

The following candidates have passed in the subjects indicated:

**SURGERY.**—R. Bobo, J. M. Moran, D. D. Stidston, L. D. Williams.  
**MEDICINE.**—P. V. Bamford, R. Bobo, S. B. Browning, K. Roberts, D. Jacobson, E. H. Waller.  
**FORENSIC MEDICINE.**—B. Best, L. O. Jaggassar, H. Rundstrom.  
**MIDWIFERY.**—B. Best, J. de Rosa, B. Elliott, L. J. Lawrie, L. W. Rose, D. D. Stidston, N. W. Wood.

The diploma of the society has been granted to Messrs. S. B. Browning and J. M. Moran.

### Medico-Legal.

#### ALLEGED NEGLIGENCE: JURY DISAGREE.

In the King's Bench Division of the High Court of Justice, on November 22nd, after a four days' hearing, before Mr. Justice Horridge, a special jury disagreed upon a claim brought by Edwin Battershill, a wholesale manufacturing furrier, against Alan Cowan Mann, M.B., Ch.B.Edin., of Staines, for damages for alleged negligence and lack of skill in failing to diagnose that he was suffering from a fractured clavicle after an accident. The defendant denied negligence, and counter-claimed for £1 10s. fees.

Mr. Ernest Charles, K.C., and Mr. Rowland Thomas (instructed by Messrs. Saunders, Sobell and Co.) appeared for the plaintiff; Mr. A. Neilson, K.C., and Mr. H. C. Dickens (instructed by Messrs. Hempson) appeared for the defendant.

#### The Plaintiff's Case.

Mr. Charles, in his opening, said that on December 6th, 1925, whilst Mr. Battershill was staying at Staines, he slipped as he was approaching the house of his friends, falling with great violence on his left shoulder. Dr. Mann examined the shoulder, and assured him that nothing was broken, but advised him to put his arm in a sling. The pain being greater the following day, Dr. Mann made a further examination, and assured Mr. Battershill again that nothing was broken. On December 9th Dr. Mann told him he could return to work on December 14th, and Mr. Battershill, though suffering intense pain and the loss of the use of three fingers, did so. On December 15th Mr. Battershill saw Dr. Lester Samuels of High Street, Whitechapel, who immediately told him he was suffering from a severe fracture of the collar-bone. An x-ray photograph, taken by Dr. Marsh, radiologist, confirmed this diagnosis, showing that the broken parts of the bone overlapped by 1½ inches. Counsel said any competent doctor, using reasonable diligence, would have had Mr. Battershill's shoulder x-rayed at once, and would then have seen the fracture. An operation was performed, which restored to Mr. Battershill the use of his arm, but, whereas it would have been a simple matter if it had been performed at once, it was, in fact, a serious matter owing to the neglect of the injury.

A number of expert witnesses were called by both sides in addition to the parties interested. For the plaintiff Sir George

Lenthal Cheatle, surgeon to King's College Hospital, was called, and, in answer to the judge, he thought that, from the x-ray photograph, any competent man could have detected the fracture with his hand. If Dr. Mann happened to be right—that is, as to the impossibility of finding the fracture—he thought Dr. Mann should have advised the patient to be x-rayed.

#### The Defendant's Case.

Mr. Neilson, opening for the defence, said that Dr. Mann's appointments, as medical officer of health to the Staines Urban District Council and medical officer to the Staines Hospital and Staines Union, showed that he was regarded as a competent and careful medical practitioner. Counsel submitted that the most likely course of events was that the pieces of bone remained end-to-end until after December 13th, and overlapped only at a later date. If that were so and the bones did not at first overlap, the treatment by Dr. Mann was correct even if there were a fracture.

Dr. Mann, in evidence, said when he first saw Mr. Battershill he suspected a fracture, but on examination he could find no displacement of bone whatsoever. He told him to put his arm in a sling and go to bed, and he considered that was the proper treatment in view of what he had found. He did not think an x-ray photograph would have been of any service in view of what he found.

Mr. Charles (cross-examining): You belong to the Medical Defence Union?—Yes.

Do you agree with this—in the annual report: "In conclusion, the President emphasizes the urgent desirability of an x-ray examination being made in every case of injury to a bone or joint"?—I have never seen that before.

Further cross-examined, Dr. Mann said that in his view the displacement of the two parts of the collar-bone was due to the breaking of the periosteum, which had kept the ends in place between December 13th and 15th. The periosteum could be torn by a movement of the arm or a bump on the shoulder or the elbow.

Horridge, J.: With that possibility before you, you thought it wise to allow Mr. Battershill to go to London to work?—Yes.

And to go without having taken an x-ray?—Yes.

Sir Robert Jones, Bt., said that for a fracture of that kind one treatment was to order the patient to keep the arm in a sling. Having seen the x-ray photograph, he considered that, personally, he would not have attempted to manipulate the fracture at all, as the bones, if left in the position in which they were, would unite satisfactorily. Answering the judge, he would not have sent the patient out to his business if the fracture were as shown in the x-ray photograph.

Mr. Frank Romer, consulting surgeon to the Jockey Club and the National Hunt Club, said that he personally would have sent the plaintiff to his business, though he admitted that if he knew there was a fracture he would strap the arm to prevent further slipping of the bones.

Sir Joseph Skevington, senior surgeon and radiologist at the King Edward VII Hospital, Windsor, and Sir Herbert Waterhouse, consulting surgeon to Charing Cross Hospital, and president of the Medical Defence Union, also gave evidence favourable to the defendant.

Mr. Justice Horridge, in his summing up to the jury, said the case was a very important and serious one. If a general practitioner agreed for reward to attend a patient he had to exercise all reasonable care and skill. He was not bound, however, to have the attainments of a Harley Street specialist, or to know the most recent discovery in medical science unless it was reasonably well known to the profession.

The jury disagreed, as stated, and were discharged.

### Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

THE House of Commons took the report stage of the Merchandise Marks Bill on November 22nd and 23rd. The rapid progress of this and other measures gives ground for hope that the Government will succeed in passing into law before the session ends most of the measures which it has asked Parliament to carry. These include the University of London Bill, the Coroners Bill, and the Public Health (Smoke Abatement) Bill, all of which have been under discussion in the last few days. The University of London Bill has still to go to a standing committee, but has strong Government support. The Smoke Abatement Bill awaits report. No quorum was obtained for consideration of the Coroners Bill in Grand Committee on November 24th, and further progress with the bill this session is unlikely. Time was left at the end of the week in the Commons for a debate on the continuance of the Emergency Regulations, but owing to the advance towards a coal settlement the Government hoped to be able to drop most of them.

The House of Lords had a second reading debate on the Electricity Bill. The Lords have given a first reading of a Poor Law Bill, introduced by the Ministry of Health. November 25th was named for the second reading of this bill, which is purely a codifying and consolidating measure, designed to prepare the way for the promised Poor Law reform.

**The University of London Bill.**

Lord Eustace Percy (President of the Board of Education) moved the second reading of the University of London Bill in the House of Commons on November 19th. It proposed, he said, to appoint commissioners to draw up statutes for the University in general accord with the report of the committee presided over first by Lord Ernle and later by Mr. Hilton Young. The committee reported that the University had no financial resources for the development of teaching and research save the balance of examination fees. The committee thought that present and prospective grant-governing committees should be able to deal with a central university body. The bill proposed to give representation on the Senate to the constituent schools of the University and to establish a Finance Council. The Board of Education had nothing to do with the bill nor would it have anything to do with the control of the University when the bill passed. One object of the bill was to get rid of the control of the finance of the University by the purely departmental and bureaucratic University Grants Committee. Dealing with criticisms of the bill's proposal to eliminate the nominated third on the Senate, Lord Eustace said it was only by chance that this nominated third represented an outside independent element. It contained, for instance, representatives of the Royal College of Physicians and of the Royal College of Surgeons, but at the present moment there was no representation of the medical schools. He gave an assurance that there was no intention to interfere fundamentally with existing schools in the University.

Mr. Trevelyan, for the Labour party, hoped the bill would receive a second reading.

Dr. Graham Little moved the rejection of the bill. He said he had been elected to Parliament in 1924 because he opposed the reconstitution of the University on the lines of the Haldane Report. There were forty-four schools in the University. The Faculty of Medicine had between 3,000 and 4,000 students. The bill was an attempt to wreck the independence of the schools, of the University, and of the students. The theological colleges had said they would not remain in the University if regulations curtailing their freedom were enforced. He was convinced that the medical schools would follow this example. One medical school had for many years refused to take the grant from the Board of Education. Another was threatened, a few years ago, by the Treasury Grants Committee with a cessation of the grant unless it consented to become a special school of medicine, instead of remaining a general school. The school, which had been a school of medicine for more than a hundred years, refused to modify its character. It worked out its own salvation and became able to support itself, and, when it had achieved that consummation the Treasury Grants Committee gave it the grant. It was useless for Lord Eustace Percy to express sympathy for university independence and then to devise machinery which must destroy that object.

Sir Alfred Hopkinson hoped that the questions raised by the bill would be settled as soon as possible. Dr. Little's motion for rejection was not pressed to a division. The bill was read a second time and sent to a standing committee.

**Lead Poisoning Bill.**

The House of Lords went into Committee on the Lead Paint (Protection Against Poisoning) Bill on November 18th. This bill has passed the House of Commons. Lord Arnold moved to insert a new clause prohibiting, from November 19th, 1927, the use of lead paint in painting the interior of buildings, save for artistic purpose, or in the process of fine lining or in accordance with a special order of the Home Office. Lord Arnold said the bill as it stood was a breach of the Geneva Convention of 1921. Every year some hundreds of men suffered from plumbism, and forty or fifty died from its effects. Experience would not support the Government's contention that regulations would stop or materially alleviate the injury done by lead paint poisoning. Thirteen years of regulation in the pottery industry had not stamped out lead poisoning. The Home Secretary had lately admitted that in one firm in the Potteries three cases of lead poisoning had occurred this year, one fatal. The Home Secretary had remarked that regulations had not been carried out. Lord Arnold contended that enforcement of regulations would be more difficult in house painting, where men did not work in masses. Lord Desborough, for the Government, had said that the position had been changed since 1921 by the introduction of wet-rubbing, and that great things were expected from a waterproof sandpaper. Lord Arnold asked whether the wet-rubbing process did not cause a cream to be formed, which got under the nails of the men who were working and into the system. He remarked that the Government itself was not confident about the bill.

The Bishop of Southwark contended that the only way of dealing with the problem was to prohibit altogether the use of lead paint.

Lord Desborough said the Government considered that action by regulations was possible at once, and would save many lives. No part of the British Empire had ratified the draft Geneva Convention of 1921 on the use of lead paint, and the Scientific Committee of the International Labour Conference had preferred a system of regulation to the prohibition of lead paint for internal work. The Government regulations for the prevention of dust and in regard to scraping and rubbing down paint would apply to external as well as to internal work.

The proposed new clause was defeated by 45 to 23.

The first clause of the bill proposes, among other things, to prohibit "dry rubbing down and scraping." The wet process of rubbing had the strong endorsement of Sir Thomas Oliver.

Lord Desborough said that the Home Office regulations would provide that every surface must be deemed to be painted with

lead unless the contrary were proved. The amendment was withdrawn.

On Clause 2, which prohibits the employment after November 19th, 1927, of any woman or young person in painting any part of a building with lead paint, Lord Balfour of Burleigh moved that women be not excluded. Only some hundreds of women would be affected, and they ought to be allowed to choose for themselves. The medical theory that women, as women, were more susceptible to lead poisoning than men dated from the days when very poorly paid women in large numbers were engaged on dangerous processes in the Potteries.

Lord Dawson of Penn doubted whether the case for the special protection of women was strong enough to justify their exclusion. He would place more reliance on the women themselves than on any regulations in deciding whether they should undertake painting. Women were precluded from entering many occupations because they were physically weaker than men, but painting was a skilled trade to which they were physically suited, unless they could be proved to be specially prone to the poison of lead. The figures at present available appeared to show that lead attacked women, especially young women, more often and more severely than men. But these figures were mainly taken from old days in the Potteries when women largely undertook the less skilled and more dangerous forms of work. There was ground for the view that a large part of the proclivity of women was the result of economic position rather than of sex. Until a further inquiry was undertaken in the light of modern knowledge he doubted whether there was a case for excluding women from the painting trade. It had been established that the respiratory tract was far and away the most important route whereby lead entered the system. Dirty fingers and unclean mouths had indirect effect by making people unhealthy and lowering their resisting power. If it were true that by substituting wet for dry methods the proposed regulations would eliminate the dust, quite possibly the greater proclivity of women would fall nearly to zero. Lead produced abortion and miscarriages, but he ventured to think that women were quite capable of protecting themselves. Dust, and dust only, mattered, and if the dust was prevented from entering the respiratory tract the women would not abort. The figures showing that lead poisoning, in bringing about abortion, often went through the male as well as the female were most interesting as well as tragic. Where the wives had never worked in lead mines and the men did so, 40 per cent. of a given number of pregnancies ended in miscarriage. There the poison was carried by means of the man, and other figures bore that assumption out. If women were excluded and men left, but the regulations were bad, miscarriages would still occur. If the regulations were good, as he believed them to be, women and men would alike be protected. He called attention to the fact that by Clause 1 of the bill the Home Secretary could order a medical examination, which would often discover the early stages of lead poisoning before the person had any symptoms. He hoped that through the activities of the Industrial Research Council means would be found whereby it could be ascertained by some biochemical test which individuals were prone to lead poisoning. A large number of people could breathe lead with apparent impunity, just as large numbers of people could drink alcohol with comparative impunity. There were others who, after a fortnight's work in lead, were apt to get poisoned.

Lord Haldane suggested that the question whether women were in greater danger of lead poisoning than men should be referred for inquiry to the Medical Committee of the Privy Council or preferably to the Committee on Civil Research.

Lord Desborough said that if the bill were shelved for inquiry it could not pass this session. Under the Women and Young Persons (Employment in Lead Processes) Act, 1920, women were not allowed to be employed in a great many processes involving the use of lead. The balance of medical opinion was overwhelmingly on the side of the views on which the policy of successive Governments for thirty-five years had been based. The opinion of Sir Thomas Oliver was: "On the whole females, particularly young females, suffer more severely from plumbism than males." He went on to say: "My contention is that it is largely owing to the power of lead to inflict harm upon the reproductive organs of women that the female sex is so liable to be adversely influenced by the metal." That contention was at the bottom of the regulations which had been adopted by Parliament. "Sir Thomas Oliver had also said: 'An interesting point in regard to maternity and plumbism is that, while the expectant mother does not show any sign of plumbism and is apparently not suffering from lead poisoning, she transmits to her babe such a legacy of lead that the infant is born dead or dies shortly after birth.' In his book on lead poisoning and lead absorption, which was written in conjunction with Sir Kenneth Goadby, Sir Thomas Legge stated unequivocally that women are more susceptible to poisoning by lead than men. The Special Commission on unhealthy processes appointed by the first International Labour Conference, which met under the Treaty of Peace at Washington in 1919, had passed unanimously a resolution stating that, although absolute proof was lacking that women were considerably more susceptible than men, their role as mothers made it necessary to consider special precautions. One of the results of this Commission was the Employment in Lead Processes Act. The Commission recommended that the subject of women and painting should be referred to a later conference. This was done, and the painting industry was considered by a conference in 1921, and a draft Convention was adopted by it, containing the provision for the exclusion of women which had been included in the Government's present bill. Lord Desborough also quoted from a publication of the International Labour Office which said: 'All agree that in women lead poisoning assumes a more severe form (manifesting itself in convulsions and amaurosis, etc.) than in men. . . . It is not necessary for the mother to be affected by lead for the children to develop symptoms of lead poisoning.'

Lord Phillimore hoped that after Lord Dawson's temperate and, in the House would not pass prohibitive medical question.

The amendment not to exclude women was defeated by 35 to 17. The House then agreed to the remaining clauses and reported the bill without amendment.

### Acute Poliomyelitis.

On November 22nd Viscount Sandon asked the Minister of Health if, to obviate the danger of infantile paralysis being spread by reason of boys being withdrawn from infected schools by parents, he would take steps to prevent any school so infected from being closed down or the boys leaving. Mr. Chamberlain (Minister of Health) replied that he was not empowered to take the course suggested, but was always ready to arrange for the medical officers of his department to confer with the school authorities on the precautions appropriate to any outbreak of infectious disease.

The Minister of Health, on November 23rd, said that the following table (here slightly abridged) gave the particulars, so far as they were available, of the numbers of cases notified and deaths recorded from acute poliomyelitis and polio-encephalitis in England and Wales and certain European countries in six-monthly periods in 1925-26.

| Country.                | First Six Months of 1925. |         |                               | Second Six Months of 1925. |         |                               | First Six Months of 1926. |         |                               |
|-------------------------|---------------------------|---------|-------------------------------|----------------------------|---------|-------------------------------|---------------------------|---------|-------------------------------|
|                         | Cases Notified.           | Deaths. | Cases per Million Population. | Cases Notified.            | Deaths. | Cases per Million Population. | Cases Notified.           | Deaths. | Cases per Million Population. |
| England and Wales ...   | 132                       | 79      | 3                             | 230                        | 77      | 7                             | 136                       | 57      | 3                             |
| Denmark ...             | 31                        | 2       | 9                             | 84                         | 2       | 25                            | 12                        | 2       | 4                             |
| Finland ...             | 14                        | 2       | 4                             | 14                         | 2       | 4                             | 8                         | 2       | 2                             |
| France ...              | 80                        | 2       | 2                             | 142                        | 2       | 4                             | 70                        | 2       | 2                             |
| Germany ...             | 131                       | 2       | 2                             | 255                        | 2       | 4                             | 115                       | 2       | 2                             |
| Holland ...             | 12                        | 4       | 2                             | 20                         | 5       | 3                             | 8                         | 2       | 1                             |
| Italy ...               | 217                       | 2       | 5                             | 383                        | 2       | 10                            | 97                        | 2       | 6                             |
| Norway (towns only) ... | 17                        | 0       | 21                            | 70                         | 8       | 88                            | 5                         | 1       | 2                             |
| Sweden ...              | 105                       | 2       | 17                            | 400                        | 2       | 66                            | 85                        | 2       | 14                            |
| Switzerland ...         | 24                        | 2       | 6                             | 69                         | 2       | 18                            | 9                         | 2       | 2                             |

The number of cases notified in England and Wales during the nineteen weeks ended November 13th, 1925, was 891 (23 per million population). The number of deaths in this period in England and Wales and corresponding figures for cases and deaths in other European countries are not at present available. The number of deaths per million mid-year population in England and Wales for the three six-monthly periods equalled 2, 2, and 1.

### Smoke Abatement Bill in Grand Committee.

A Grand Committee of the House of Commons, which included Dr. Fremantle and Sir Richard Luce, began consideration on November 18th of the Public Health (Smoke Abatement) Bill. The first clause provides that a chimney (not of a private dwelling house) sending forth smoke in such quantity as to be a nuisance may be dealt with summarily, notwithstanding that the smoke was not black. To an amendment to insert the word "black" before "smoke," Mr. Neville Chamberlain objected. He said Lord Newton's Committee examined nearly 150 witnesses, who were almost unanimous that the limitation of the present law to black smoke should be removed. He had watched the chimneys of certain works pouring out white smoke which contained the fumes of arsenic and lead, and as the law stood no local authority could take proceedings. Moreover, it was impossible for a central body to define black smoke or the quantity which could be emitted without a nuisance. Mr. Greenwood agreed that "smoke" should include all noxious emanations from chimneys which meant positive injury to health and vegetation. Commander Astbury said that most councils allowed the manufacturer two minutes of black smoke while firing to get up a pressure of steam, and thought this practice should continue. Dr. Fremantle said the bill contained safeguard after safeguard for industry. Those who were keen on getting some measure of smoke prevention from the public health point of view feared that nothing would be done. The amendment was negatived, as was also one enjoining the Ministry of Health to fix standards for smoke.

On the proposal of the bill to make smoke include soot, ash, grit, and gritty particles, Sir Kingsley Wood said it was just as detrimental for these to be emitted as black smoke. Mr. Williams said that forced draught would reduce black smoke, but would produce a greater emission of grit. So would the use of powdered coal as fuel blown on the furnaces. Major Birchall repudiated such protests on behalf of manufacturers. Sir Kingsley Wood said the Ministry of Health did not apprehend that any nuisance would follow the use of proper steps were taken. Fourteen towns, Bradford, had power under the Bolton, and the emission of grit and gritty particles. Mr. Jephcott said that in the new station of the Birmingham Electricity Committee they were spending £30,000 in an effort to eliminate grit, but so far had failed. The amendment to omit grit and gritty particles was defeated.

Asked to explain what processes would be exempted under the bill, Sir Kingsley Wood said that, broadly speaking, they were the Sheffield steel processes. Mr. Chamberlain said it might be true that Pittsburgh had been able to make steel without smoke, but Sheffield had not the processes needed, and in its present

difficulties could not be forced to adopt them. Mr. Albery asked that exemption should also be granted to cement works, which threw fine dust up the chimney that did no appreciable harm. Evidence in medical reports from Germany and this country was that the health of the cement worker was not affected in any exceptional way. Mr. Chamberlain said he was advised that the emission of white smoke and dust particles from cement works had not in fact been found to be a nuisance.

**The International Opium Convention.**—Sir Austen Chamberlain, in an answer to Mr. Campbell, said that a ratification of the International Opium Convention had been deposited which covered all parts of the British Empire except Canada and the Irish Free State. Of foreign signatories, only Portugal and the Sudan, so far as the Government knew, had deposited ratifications. The Hague Convention of 1912 continued in force between the States which were parties to it.

**Encephalitis and Vaccination.**—On November 22nd Mr. Chamberlain told Mr. Groves that he had drawn the attention of the Committee on Vaccination, now sitting, to cases of death from encephalo-mylitis after vaccination. One of the terms of reference of this committee was to inquire into and report on the practical methods which were available in the light of modern knowledge to diminish or remove any risks which might result from vaccination. On November 22nd Mr. Trevelyan Thomson asked whether encephalo-mylitis was mentioned as a cause of death on the certificates of death in the case of the seven deaths from that disease which occurred shortly after vaccination; whether an inquest was held on any of the cases in question; and whether the lymph used for the vaccinations was issued by his department. Mr. Chamberlain replied that he was informed that, so far as it had been possible to identify these fatalities, in none of the seven deaths was "encephalo-mylitis" mentioned on the practitioner's certificate as a cause of death. An inquest was held in one case. In four of the seven cases the lymph used for the vaccination was issued by his department, and in one instance a proprietary lymph was used, but no information as to the source of the lymph used in the remaining two cases was available. The deaths to which he assumed reference was made occurred in 1912, 1922, and 1923.

### Notes in Brief.

The Minister of Health cannot undertake to introduce legislation to waive, in cases where proper medical evidence is given on the date when sickness commenced, the rule that sickness must be notified within three days of its occurrence. The official view is that prompt notification of illness is essential to the proper administration of sickness benefit.

Mr. Chamberlain told Admiral Beamish that he would consider whether the terms of the Departmental Committee now investigating the chemical treatment of flour should be extended with a view to its making an authoritative statement on the dietetic value of white bread. The committee could not take up this subject till it had disposed of the matters already referred to it.

Lord Eustace Percy has stated that some preliminary tests and observations have been made among school children on the use of glass which allows the ultra-violet rays of the sun to reach them. Any general recommendation on the subject would, however, be premature.

Mr. Chamberlain has received a report from the local authority which seems to show that the mortuary at Dover is reasonably adequate. Asked whether the coroner had stated that he had received complaints from every doctor in Dover that the mortuary was insufficient, Mr. Chamberlain declined to give any further answer.

## Medical News.

THE annual dinner of past and present students of the Bristol Medical School will be held on Thursday, December 2nd, at the Victoria Rooms, Clifton, Bristol, at 7 for 7.30 p.m. The chair will be taken by Professor E. Fawcett, F.R.S. The guest of the evening will be Professor J. T. Wilson, F.R.S. (Cambridge University). Local practitioners, as well as old Bristol students, are cordially invited to attend. Application for tickets should be made without delay to Mr. W. A. Jackman, 15, Mortimer Road, Clifton, Bristol.

THE centenary of the death of Pinel, to whose efforts was largely due the introduction into France of milder methods for the treatment of the insane, was celebrated by the Académie de Médecine in Paris on October 26th, when the General Secretary, Professor Achard, delivered a memorial address.

AT the meeting of the Röntgen Society to be held at the British Institute of Radiology, 32, Welbeck Street, W.1, on Tuesday, December 7th, at 8.15 p.m., Mr. W. V. Mayneord will read a paper on an x-ray study of the crystal structure of some biological objects. Mr. Cuthbert Andrews will give a demonstration on the scintroscope, a new instrument for serial radiography.

A MEETING of medical practitioners to discuss the question of treatment for tuberculosis has been arranged by the Mayor of Lambeth, Dr. R. S. Pearson; it will take place at his house, 193, Clapham Road, S.W. (near The Swan, Stockwell), on Thursday, December 16th, at 4 p.m.

At the meeting of the Post-Graduate Hostel to be held at the Imperial Hotel, Russell Square, W.C.1, on Tuesday, November 30th, at 9 p.m., Mr. W. Ernest Miles will give an address on fistula. On Wednesday, December 1st, at the same hour, Dr. M. A. Cassidy will speak on precordial pain. Dinner will be served at 8 p.m. (price 5s.), and coffee and biscuits at 10 p.m. (price 6d.). All medical practitioners are welcome.

The Fellowship of Medicine announces that on December 2nd, at 5 p.m., Dr. John Parkinson will lecture on cardiac emergencies at the Medical Society, 11, Chandos Street, W.1; the lecture is free to medical practitioners. From December 6th to 18th, at the Infants Hospital, Vincent Square, a special course in infants' diseases will be held for medical officers of welfare centres and others interested. Lectures and clinical demonstrations will be given each afternoon and visits will be paid to the model pasteurizing plant at Willesden, the venereal diseases centre, Holborn, and to the Nursery Training School at Hampstead. Courses in obstetrics can be arranged at Queen Charlotte's Hospital and the City of London Maternity Hospital. Clinical assistantships can be obtained through the Fellowship at the Samaritan Hospital. The following special courses will be held in January: medicine, surgery, and the specialties, at the Prince of Wales's General Hospital; cardiology, at the National Hospital for Diseases of the Heart, for which early application is desirable; diseases of children, at the Children's Clinic and the Royal Free Hospital; and psychological medicine, at the Bethlem Royal Hospital. Copies of all syllabuses and of the general course programme may be obtained from the Secretary to the Fellowship, No. 1, Wimpole Street, W.1.

SIR ROBERT ARMSTRONG-JONES, C.B.E., M.D., of Plas Dinas, Carnarvon, and Dr. William Evans Thomas of Coodladwr, Llanuwchllyn and Ystrad Rhondda, have been nominated as sheriffs for Carnarvonshire and Merionethshire respectively.

In connexion with the scheme for providing spa treatment for trade patients a deputation from the General Federation of Trade Unions visited Bath last week and investigated the local facilities for treatment of rheumatic diseases under the guidance of the chairman of the Baths Committee, Councillor C. H. Hacker, and Mr. John Hutton, director of the baths, who is also honorary secretary of the British Spas Federation, which is responsible for the scheme. The proposals provide for the treatment of insured persons suffering from rheumatic diseases which are likely to yield to spa treatment, using existing facilities at spas in such a way as not to interfere with the regular visitors. It is hoped to link up the scheme with the mineral water hospitals.

DR. ALEXANDER SCOTT was called to the Bar by the Middle Temple on November 17th.

THE Master and Wardens of the Society of Apothecaries have issued invitations to the winter livery dinner at Apothecaries' Hall, Blackfriars, on Tuesday, December 14th.

A CHAIR of biological chemistry has been founded at the medical faculty of Naples, with Professor Quagliariello as its first occupant.

THE first Polish school for nurses has recently been founded in one of the hospitals at Warsaw by American Jews.

DURING the week ending October 16th 5 cases of plague with 3 deaths, 16 cases of cholera with 11 deaths, and 25 cases of small-pox with 10 deaths were reported by the Far East Bureau at Singapore.

At the eighth annual general meeting of the Industrial Welfare Society, on November 17th, the report was presented for the year ending June 30th, 1926. The steady increase in the extent and value of the work was the subject of a congratulatory message from H.R.H. the Duke of York, who during the year had visited fifteen firms associated with the society. The report contains an account of the progress made, with special reference to the organization of welfare schemes, the appointment of supervisors, the work of the information department, and various conferences, lectures, and other propaganda activities.

THE Alvarenga prize of the College of Physicians of Philadelphia has been awarded this year to Drs. P. S. Pelouze and Frederick S. Schofield for an essay entitled "The Ganophage." It is announced that essays for the 1927 prize must reach the Secretary of the College of Physicians, 19, South 22nd Street, Philadelphia, on or before May 1st. The value of the prize is about 300 dollars.

THE following five members of the medical profession have been appointed justices of the peace for Glasgow: Dr. John Glaister, jun., Dr. R. T. Halliday, Dr. William Lawson, Dr. Henry L. G. Leask, and Professor Archibald Young, M.D.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 3861, 3863, 3865, and 3867** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

**EDITOR** OF THE **BRITISH MEDICAL JOURNAL**, *Aitiology Westcent, London.*

**FINANCIAL SECRETARY AND BUSINESS MANAGER** (Advertisements, etc.), *Articulate Westcent, London.*

**MEDICAL SECRETARY**, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Basillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

## QUERIES AND ANSWERS.

### TINNITUS IN MÉNIÈRE'S DISEASE.

"H. S." (Leeds) asks for suggestions for the relief of the constant "singing noises" in a case of Ménière's disease. Bromides, potassium iodide, hydrobromic acid, gelsemium, and adrenaline have been tried.

### CHILBLAINS.

DR. M. STEWART-SMITH (Northwood) writes: I have had considerable success with the high-frequency vacuum electrodes, applied after iodex has been smeared on to the affected parts. Radiant heat is then used after the high-frequency treatment.

### RECURRENT ULCERATION OF THE MOUTH.

"A. Y." seeks advice on the following case: A man, aged 25, has frequently recurring small ulcerations of tongue and mucous membrane of mouth generally. The tongue is often painful in parts without any obvious cause. About seven years ago a pipe snapped in his teeth and caught the tongue, and this was, perhaps, the origin of the trouble. Treatment, so far tried without success, as follows: (1) Diet: all condiments and spices forbidden; (2) no smoking; (3) antiseptic mouth-wash (potassium permanganate 1 in 10,000, and also sometimes dibromin 1 in 5,000 instead); the tender spots are treated with glycer. alum; (4) a strongly alkaline mixture was ordered for three or four weeks to check acidity. The teeth are quite healthy. These ulcerations have been occurring for some years, and the above treatment seems to have failed to check them. The general condition of the patient is satisfactory.

### NERVOUS RETCHING.

"H. T." writes to ask for suggestions for overcoming the retching excited by the introduction of a denture. The patient is a very nervous man, who retches immediately any foreign body (except food) comes into contact with his teeth, so that he even finds it difficult to smoke a pipe. It has now become necessary for him to wear a denture, but he is unable to do so on account of his hypersensitiveness.

### INCOME TAX.

#### Vacant Consulting-Room.

"E. P." has been living on the outskirts of London and using a consulting-room in the medical quarter. For reasons of health he has moved into the London area and now practises in his own residence. He has given up the use of his consulting-room, but, owing to temporary inability to sublet or otherwise dispose of it, has since incurred the expense of paying nine months' rent without any return. Can he deduct this expense?

\* In the case of the Granite Supply Association v. Kitton (43 Sc. L. R., 65) the court refused to allow the cost of removal to more commodious premises; we fear that the taxpayer's claim would be at least no more likely to succeed where the cause of the expense was a purely personal one, such as for reasons of health. The expense incurred by "E. P." after he had ceased to use the consulting-room seems to have been in substance an expense of removal, and therefore inadmissible in view of the above decision.

### Partnership Dissolved—Cash Basis.

"A" and "B" dissolved partnership as from June 30th, 1925, and advice is sought as to whether the firm's book debts collected since the dissolution must be accounted for for tax purposes, and, if so, as to the proper apportionment of the assessments for

1925-26 and 1926-27 between "A" and "B." The practice has been assessed on the "cash basis" for many years.

\* \* It is essential to bear in mind the fact that the income tax Acts attach liability to the earnings or profits of a practice whether received in cash or still owing. The reason for the acceptance of the amount of the cash received as the basis for assessment is that that figure is readily ascertainable and is in the long run the same as the value of the bookings; but it is not the receipts as such which are being taxed, but the profits of the year of assessment. In the present case the profits of the year 1925-26 have been estimated on the average of the three years 1922-1924, taking the gross earnings as the amount of the cash receipts for those years, but the method of arriving at the assessment does not affect the primary fact—namely, that it relates to and is in respect of the profits of the year ending April 5th, 1926. Consequently Dr. "A" should bear the tax relating to quarter of half of the gross assessment for 1925-26, and no portion of the 1925-27 assessment is applicable to him. Whether or not the cash received after June 30th, 1925, should be brought into the calculation of the 1926-27 assessment depends on whether Dr. "B" wishes to continue to be assessed on the cash basis. He is entitled to reject it for the future and to calculate the gross receipts according to the value of the fees receivable for the work done, but of course the cash basis is very much more convenient in practical working.

#### Car Allowance.

"I. G." bought a new car in April, 1925, for £195, and sold it in July, 1926, for £70, buying a new car of similar make and power for £190. He has claimed an allowance of £120, but the inspector regards £40 of this as a capital loss, that amount "being the difference between the price of a second-hand car fifteen months old and the price" actually received.

\* \* We fail to see the argument unless the second car was of a more expensive type than the car displaced. If, for instance, the old car was an open tourer and the new one of the enclosed type, then there is some substance in the contention that inasmuch as an improvement had been effected some of the cost must be placed to capital. In the absence of some special feature of that kind we disagree with the inspector's view, and consider that it is irrelevant to bring hypothetical figures into the computation; if "I. G." replaced one car by a similar one, he is entitled to the allowance without such a deduction as is suggested.

#### LETTERS, NOTES, ETC.

##### GOOD AND BAD DIETS.

"INQUIRER" writes: I think everyone reads Colonel McCarrison's writings with much interest and profit, and that published on October 23rd (p. 739) tempts me to ask if he or any other recognized authority would detail a good daily diet for the Britisher, with particular reference to the eating of raw vegetables. We read of individuals and sects who maintain that vegetables should be eaten raw, but I have yet to see anyone do so. As youngsters we stole and ate raw carrots and turnips, but that natural instinct has gone with most adults, evidently to our misfortune, to judge from McCarrison's experiments. Are we to give up cooking our vegetables and fruits, either by boiling or steaming, and give ourselves stoically to taking our vegetables raw? I am sure many would be willing to try if one with McCarrison's authority outlines a diet, detailing the vegetables and fruits to be eaten raw.

##### CYTOLYTIC TREATMENT OF CANCER.

DR. MICHAEL C. GRABHAM, in a pamphlet entitled *The Mastery of Cancer* (published by Messrs. H. K. Lewis and Co., Ltd.), states that some success has been obtained in the treatment of advanced cancer by the local action of trachoma exudate. In this connection he refers to the publication of A. Fleming (*Proceedings of the Royal Society*, 1922), in which the lacrymal secretion was shown to be endowed with bacteriolytic, and a diplococcus lysodeikticus. Dr. Grabham is

a medical practitioner in Funchal, found that a few drops of trachoma exudate, when injected into a growing carcinoma, caused immediate inhibition of the vitality of the malignant tissues, and, ultimately, their disintegration, with little or no disturbance. Two cases are mentioned particularly: the first was one of cancer of the uterine cervix in a woman aged 60, and the other of carcinoma of the breast in a woman aged 40. In both complete recovery is stated to have followed the application of the purulent trachoma exudate. Dr. Grabham is inclined to believe that the micrococci or the lacrymal lysozyme is the active agent, and invites further research with a view to establishing the reliability of this method of treatment. He states that seventeen patients have been treated already in Madeira.

##### COMMON SALT AND CANCER.

MR. FREDK. T. MARWOOD, J.P. (Pleasington, Lancs), writes: In the *JOURNAL* of October 30th (p. 803) there is an extract from the annual report of Dr. L. J. Picton, medical officer of health for Winsford. In it there appears the following passage: "The staple industry of Winsford is the manufacture of salt from

brine. As the mortality rate from cancer at Winsford is no higher than elsewhere, the theory that salt has anything to do with cancer has, says Dr. Picton, no support." As a layman deeply interested in the subject of salt in relation to cancer (on observational and statistical lines only) may I be permitted to explain that in my investigations I am mainly concerned with consumers of salt, salted foods, and salt compounds, although I have not overlooked the point brought forward by Dr. Picton. There are workers amongst many deleterious compounds who pursue their avocations without injury to health. If the M.O.H. for Burton-on-Trent made the statement that because drunkenness was no higher at Burton-on-Trent than in many other places the theory that beer induced inebriation received no support, this it seems to me would be on a par with Dr. Picton's conclusions regarding Winsford and cancer.

##### SUPPLY OF DOGS FOR RESEARCH.

ON November 20th a man named Hewett was convicted by Mr. Fry, magistrate at Bow Street police court, for feloniously receiving two Irish terrier puppies, valued at £7, and for cruelly ill-treating them. He was sentenced to six months' imprisonment, with hard labour, on the first charge, and to a further month's imprisonment on the second. It appeared that Hewett had been sentenced at Leicester in 1914 to four months' imprisonment for dog stealing, but had since been working honestly. An inspector of the Royal Society for the Prevention of Cruelty to Animals said that Hewett was stopped when about to take the puppies into the School of Physiology at University College; they were in a sack, and when removed were in a state of complete exhaustion. In a published statement Dr. C. Lovatt Evans, Jodrell Professor of Physiology at University College, said that he had purchased dogs from Hewett since October 11th last. Hewett was a dealer in dogs and other animals, and provided food for the animals in the laboratory; he had signed a declaration to the effect that all the animals supplied to the laboratory were legally obtained. It is unfortunate that the laboratory should inadvertently have had dealings with a dog stealer, but it may be well to point out that the position with regard to the supply of dogs to physiological laboratories is anomalous. The police, we are informed, are by law required to take all stray dogs to the Dogs' Home, where unclaimed dogs, and those for which no ordinary purchaser can be found, are put to death. On the other hand, Parliament and the Government require various researches to be carried out which call for the employment of dogs; it does this through grants to the Royal Society and to the Medical Research Council, has a special committee for imperial research, and is deeply interested in the prevention and cure of tropical diseases. Government employs inspectors to see that all animals in laboratories are properly housed and kindly treated, and requires a return of all experiments in these laboratories to be made every year to Parliament. On the Continent and in many towns of America a university can obtain or buy animals from the dog pound kept by the police; but here a stray dog must be killed in a lethal chamber, but not by an overdose of chloroform after serving a useful purpose. In view of public comments that have followed the prosecution at Bow Street, Lord Chelmsford, Chairman of the College Committee of University College, London, has appointed a subcommittee to inquire into the supply of dogs to the School of Physiology, and the first meeting was held on Tuesday.

##### MAJORCA.

WE are indebted to Dr. A. PHILLIPS (Cotebrook, Tarporley) for information about Majorca additional to that published last week (p. 958). Dr. Phillips recommends the inquirer to obtain Chamberlain's *Guide to Majorca*, 1925, which is the "official publication of the Fomento del Turismo de Palma, Majorca." This book, written in English, is full of most useful information relating, not only to Palma, but to the whole island. It also contains two good maps and is fully illustrated.

##### A PHOTOGRAPH IN AN ADVERTISEMENT: AN APOLOGY.

WE have received from the Secretary of the Ardath Tobacco Company a letter with reference to an advertisement of cigarettes in which a photograph of Sir W. Arbuthnot Lane smoking a cigarette was included. The Secretary writes:

This photograph was selected, with others, from a large number submitted, and was purchased by us from a firm of photographers who purported to sell us the copyright. We were in total ignorance as to who was the original of the photograph, and it was not until after some of the advertisements appeared that we knew that we had inadvertently used a photograph of Sir W. Arbuthnot Lane. We need scarcely say that Sir W. Arbuthnot Lane knew nothing of this until he saw his photograph in the press as part of our advertisement. Directly our attention was drawn to this we withdrew our advertisement, and we desire to apologize to Sir W. Arbuthnot Lane and to express our regret that such a mistake should have been made, and as a mark of that regret we have had much pleasure in sending a cheque for 100 guineas to the New Health Society, in which Sir Arbuthnot Lane is so much interested.

##### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 35, 36, 37, 40, and 41 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 38 and 39.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 231.

## Harveiana Edinburgensia: RELATIONS OF WILLIAM HARVEY TO MEDICINE IN EDINBURGH.

BEING THE HARVEIAN ORATION TO THE EDINBURGH  
HARVEIAN SOCIETY

BY

SIR ROBERT PHILIP, M.D., LL.D.,

CONSULTING PHYSICIAN, ROYAL INFIRMARY, EDINBURGH; PRESIDENT-  
ELECT OF THE BRITISH MEDICAL ASSOCIATION.

FELLOW HARVEIANS.—The return of our Harveian Festival recalls from the subconscious a host of feelings to each of us: in the forefront the sense of profound reverence towards one of the *Dii immortales* of medicine; in little less degree, the sense of pride—national pride—that the unravelling of the enigma of the circulation was British born. For it is not we alone who, on the day of celebration, stand bareheaded before the perpetual monument; in every school of medicine the world over the same impulse is felt, whatever the outward expression.

The recurrence of the festival rekindles our interest in the personality of the man and the bygone times when he accomplished his work, and in the relation of that time to ours. The events of those far-off days and of this evening in the Physicians' Hall intermingle in curious intimacy—a closer intimacy than we may have hitherto realized. That is the burden of my song, and on that account I have ventured to label these pre-prandial jottings "Harveiana Edinburgensia."

Hopeless as it seems to shift the kaleidoscope so as to reveal any further facet in the precious stones unearthed by the labours of his genius, and impossible as it may be to add to the knowledge of his life, I crave indulgence in seeking to forge some links which attach William Harvey to our city, and particularly to the University and Edinburgh School of Medicine.

Partial as may be its success, the effort may not lack in interest on the occasion of the Harveian Festival which coincides so closely with the celebration of the bicentenary of the Medical Faculty. For it seems to me a reasonable view, on evidence to be presently submitted, that in the events which culminated in the creation of the Edinburgh School the manifold activities of Harvey played no insignificant part.

### HARVEY'S EARLY LIFE AND SCHOOLING.

In order to clarify the leading *motif* of this address, you will allow me, first, to recall some biographical points, familiar enough, but with special bearing on my purpose. The facts are drawn from a variety of sources. For those which bear on Harvey's life I would express my especial indebtedness to Sir Norman Moore's *History of St. Bartholomew's Hospital*, and Sir D'Arcy Power's *William Harvey*.

William Harvey was born at Folkestone on April 1st, 1578. His father was an alderman of Folkestone and filled the office of Mayor in 1600. His mother must have been a remarkable woman, and probably influenced her family (seven sons and two daughters) in high degree. On her tombstone she is described as

"A Godly harmles Woman: A chaste loveings Wife;  
A Charitable quiet Neighbour: A comfortable friendly Matron:  
A provident diligent Husewife: A carefull tender-hearted Mother.  
Deere to her Husband: Reverenced of her Children:  
Beloved of her Neighbourrs: Elected of God."

Harvey was educated at the King's School, Canterbury (five years), and passed to Cambridge (Caius College) at the age of 16. The selection of Caius College seems an early indication of his direction towards medicine, for Caius, the founder of the college, besides being a classic, seems to have been one of the first exponents of practical anatomy in this country. Caius College had the privilege of receiving annually for dissection the bodies of two criminals who had undergone capital punishment. Harvey took the degree of B.A. in 1597.

About this date his passion for travel showed itself, and in 1598 he set out for Italy by way of France and

Germany. Anatomist and physician in embryo, he made for Padua—which had been the home of Vesalius and was at the date of Harvey's residence the school of Fabricius (*de Aquapendente*). Padua was the university at which Caius had taught. In each session, which commenced with an oration in praise of medicine, followed by High Mass and the Litany, the entire body was dissected twice in public by the professor of anatomy.

Fabricius must have been a remarkable man. Admittedly most learned, he was given precedence of all other professors, with a right to wear a robe of purple and gold and the golden collar of the Order of St. Mark. In his old age he was granted an annual pension of a thousand crowns. Harvey seems to have been singled out by Fabricius, then aged 61, who became his close friend. At the time of Harvey's arrival Fabricius was engaged in original work on the circulation, especially the veins. Harvey was admitted Doctor of Medicine of Padua in 1602. The diploma, dated April 25th, records that "he had conducted himself so wonderfully well in the examination, and had shown such skill, memory, and learning, that he had far surpassed even the great hopes which his examiners had formed of him. They decided therefore that he was skilful, expert, and most efficiently qualified both in arts and medicine, and to this they put their hands, unanimously, willingly, with complete agreement, and unhesitatingly." The diploma of Padua granted to Harvey leave to practise and teach in every land and seat of learning.

### HARVEY AND THE ROYAL COLLEGE OF PHYSICIANS OF LONDON.

On returning to England Harvey fixed his residence in London. He took the degree of Doctor of Medicine at Cambridge, and became a Member of the College of Physicians of London in 1604. Later in the same year he married Elizabeth Browne, daughter of Dr. Lancelot Browne, physician to Queen Elizabeth and to James I. His professional advance was rapid. In June, 1607, he was admitted a Fellow of the College of Physicians, and in 1609 was elected to the office of physician to St. Bartholomew's Hospital. In his application for this post he had the support of King James I and the president of the Royal College of Physicians.

In 1615 he was appointed Lumleian Lecturer—one of the earliest offices in the gift of the Royal College of Physicians, which continues till this day. The fact that it was primarily an anatomico-surgical lectureship is interesting, and emphasizes the close relation which existed in those days between the better educated physicians and surgeons. Harvey, be it noted, was a leading Fellow of the Royal College of Physicians, and we commonly think of him nowadays as a physician. The Harveian Festival of London is the central feature in the annual life of the Royal College of Physicians. Yet Harvey was conspicuously an anatomist and biologist. He held the Lumleian Lectureship for forty years, and he evidently practised surgery, for one of the clauses of his will bequeaths especially his "little silver instruments of surgery to Dr. Scarborough."

His function as Lumleian Lecturer seems to have corresponded to that of professor of anatomy. From the earliest times anatomy, as the foundation of medicine, held a high place. The lecturer on anatomy was held in supreme respect. Anatomical discourses were conducted with considerable ceremony. The fact is illustrated in Rembrandt's celebrated picture of Professor Tulp demonstrating the relations of the flexor sublimis (*perforatus*) and flexor profundus (*perforans*) of the hand in the midst of a group of colleagues of the Guild of Surgeons of Amsterdam (painted in 1632).

Harvey's attitude to the Lumleian Lectures shows the large scope of the lectureship and no less the width of his own outlook. Among the principles he laid down for himself in the conduct of his lectures are included the following:

Not to speak of anything which can be as well explained without the body or can be read at home.

Not to enter into too much detail, or into too minute a dissection, for the time does not permit.

To enforce the right opinion by remarks drawn from far and near, and to illustrate man by the structure of animals. To bring in points beyond mere anatomy in relation to the causes of diseases, and the general study of nature, with the object of

correcting mistakes and of elucidating the use and actions of parts, for the use of anatomy to the physician is to explain what should be done in disease.

It is noteworthy that Harvey's first course of lectures, delivered in 1616 (the year of Shakespeare's death), already contained in embryo his great discovery, which was only formally published in 1628. In discoursing on the thorax he says:

"It is plain from the structure of the heart that the blood is passed continuously through the lungs to the aorta as by the two clocks of a water bellows to raise water. It is shown by the application of a ligature that the passage of the blood is from the arteries into the veins. Whence it follows that the movement of the blood is constantly in a circle, and is brought about by the beat of the heart."

#### HARVEY'S RELATIONS WITH THE STUARTS.

In the midst of his scientific observations and research Harvey acquired an influential practice. He had as patients Francis Bacon, the Lord Chancellor, the Earl of Arundel, and others. And who can say whether he may not have been consulted by William Shakespeare? He was appointed Physician Extraordinary to King James I on February 3rd, 1618. In the formal language of the time, "the King, as a mark of his singular favour, granted him leave to consult with his ordinary physicians as to his Majesty's health," promising him the post of Physician in Ordinary as soon as one should become vacant. This is highly significant as showing Harvey's very close relations with the King, whose promise, although not fulfilled in his lifetime, because there was no vacancy, was implemented in his son's reign, when Harvey became Physician in Ordinary to Charles I (1631). In the College of Physicians Harvey was appointed one of the four Censors in 1613, and was reappointed on several occasions. In 1627 he was nominated one of the "elects" (one of eight), who had the duty of selecting the president and of examining candidates for licence to practise. In 1628 he became treasurer of the College, and was re-elected as treasurer in 1629. The year 1628 is still more conspicuous as being the year of the publication of his great work *Exercitatio Anatomica de Motu Cordis et Sanguinis*.

In 1629, by command of the King, he accompanied James Stuart, afterwards Duke of Lennox (aged 17), on a Continental journey, resigning his office of treasurer of the College and getting leave of absence from St. Bartholomew's. They travelled in France and Spain (apparently not Italy, where, in the north, plague was virulent). An interesting sidelight on his scientific outlook is found in a letter from Harvey to Viscount Dorchester in which, describing the countries he passed through, he wrote:

"I can only complain that by the way we could scarce see a dog, crow, kite, raven, or any other bird, or any thing to anatomise, only some few miserable people, the relics of the war and the plague where famine had made anatomies before I came."

On his return to England he renewed his interest in the College of Physicians. In 1631 he was appointed Physician in Ordinary to King Charles I, with whom he appears to have come into very close personal relations, accompanying him everywhere and joining in sport and social functions. Of the intimate terms on which he stood with King James and King Charles I there is abundant evidence in his life. More than once there are references to specimens—eggs and the like—which he showed to the King. He utilized his frequent hunting expeditions with King Charles for the purpose of dissecting deer; for example, he says:

"The game, during the three summer months, was the buck, then fat and in season; and in the Autumn and Winter for the same length of time the doe. This gave me an opportunity of dissecting numbers of these animals almost every day during the whole season. . . . I had occasion, so often as I desired it, to examine and study all the parts . . . because the great Prince, whose physician I was, besides taking much pleasure in such inquiries and not disdaining to bear witness to my discoveries, was pleased in his kindness and munificence to order me an abundant supply of such animals, and repeated opportunity of examining their bodies."

Referring to the minute embryonic heart, he writes:

"I have exhibited this point to His Serene Highness the King, still palpitating. . . . It was extremely minute indeed, and without the advantage of the sun's light falling upon it from the side, its tremulous motions were not to be perceived."

And again, with reference to a young nobleman (the eldest son of Viscount Montgomery) in whose case the King was much interested, he writes:

"I carried the young man himself to the King that His Majesty might with his own eyes behold this wonderful case: that in a man, alive and well, he might without detriment to the individual, observe the movement of the heart, and with his own hand even touch the ventricles as they contracted. And His Most Excellent Majesty, as well as myself, acknowledged that the heart was without the sense of touch: for the youth never knew when we touched his heart except by the sight and sensation he had through the external integument. . . . We also particularly observed the movements of the heart, viz., that in the diastole it was retracted and withdrawn; while in the systole it emerged and protruded."

In 1633 he accompanied the King to Scotland when His Majesty was crowned at Holyrood, at the time when ecclesiastical difficulties were rife in Scotland and Janet Geddes threw her stool at the Bishop of St. Giles. During that visit to Scotland Harvey found time to develop his biological taste, visiting the Bass Rock, which he described in interesting and graphic terms.

In 1636 Harvey visited Germany, Austria, and Italy, apparently in the entourage of the Earl of Arundel, who went to Vienna as Ambassador Extraordinary to the Emperor Ferdinand. *En route*, he stopped at Nuremberg and tried (in vain) to convince Casper Hofmann, one of his leading critics, of the truth of his views by demonstration. A letter bearing on his visit to Rome describes him as "honest little Harvey whom the Earl is sending to Italy about some pictures for His Majesty"—an interesting sidelight on his quality and culture.

In 1639 he was appointed Senior Physician in Ordinary to the King. The civil war was just beginning and Harvey accompanied the King. At the battle of Edgehill, on October 23rd, 1642, he was placed in charge of the King's sons, Charles and James. Retiring with the King to Oxford, he was admitted to the degree of M.D. on December 7th, 1642. During his stay in Oxford, in addition to the usual professional work, he devoted himself to natural science, worked at anatomy, made many dissections, and was in close touch with men who were working there, including notably Highmore and Charles Scarborough. The latter was attached to Merton College, of which college Harvey was named Warden by Royal mandate in 1645. Scarborough was admitted a Doctor of Physic in 1646.

#### LATER YEARS.

When Oxford surrendered in 1646 he returned to London, and thereafter retired largely into private life, living with his brothers Eliab and Daniel. His attachment to the College of Physicians was maintained. He was elected councillor in 1655 and 1656, and continued to hold the Lumleian Lectureship till 1656.

His last literary effort—the treatise on generation—was published in 1651. In that year he offered to build a library for the College of Physicians. This was formally handed over to the College in February, 1654. That same year the College sought to elect him president, but he declined on account of his age. In giving up the Lumleian Lectureship in 1656 he took formal farewell of the Fellows and presented his paternal estate in Kent to the College. He was succeeded in the Lumleian Lectureship by Sir Charles Scarborough, to whom he was attached by affectionate ties, and whom he had urged to come to London.

Harvey suffered much from gout, and the attacks became aggravated with the advance of years. He died at Roehampton in his brother's house on June 3rd, 1657, in his eightieth year—apparently from cerebral haemorrhage—and was buried at Hempstead, Essex, on June 26th, being followed to the grave by the Fellows of the College of Physicians "clothed in their gowns."

His devotion to the College of Physicians is further illustrated by the terms of bequest, which run:

"And first, I appoint so much money to be raised and laid out upon that building which I have already begun to erect within the College of Physicians in London as will serve to finish the same according to the design already made." And again: "Touching my books and household stuff, pictures and apparel, of which I have not already disposed, I give to the College of Physicians all my books and papers and my best Persian long carpet and my blue satin embroidered cushion, one pair of brass andirons with fire shovel and tongs of brass for the ornament of the Meeting Room I have erected for that purpose."

And in testimony of his close attachment to Sir Charles Scarborough the will reads:

"I give my velvet gown to my loving friend Mr. Dr. Scarborough"; and later, "And to Dr. Scarborough all my little silver instruments of surgery."

In thus briefly recalling some points in the life of Harvey I have sought to punctuate those which reveal to us the manner of man he was: humanist, biologist, physician with a sidelong glance towards surgery, the confidant of the best men of his time, the trusted adviser and friend of two successive sovereigns, and the supremely devoted Fellow of the Royal College. His influence in all these spheres must have been great.

"He dwelt among men: physician and sage,  
He served them, loving them, healing them;

He played on men, as his master, Phoebus, on strings  
Melodious."

#### HARVEY AND THE UNIVERSITY OF EDINBURGH.

My immediate purpose in rehearsing these points has been to inquire whether, and to what degree, his influence had bearings on events in the history of Edinburgh, and particularly of the Edinburgh Medical School.

It is indeed a remarkable fact that William Harvey, born in England, educated at Cambridge and Padua, and early and closely attached to the Royal College of Physicians of London, was, by reason of the circumstances of the times, brought into closest relationship with the monarch who, after long residence and rule in Scotland, carried to England a full knowledge of the educational and allied conditions in Edinburgh, to which city, some twenty years before, he had granted the Royal Charter founding King James's College—the Town's College—which subsequently developed into the University of Edinburgh.

William Harvey was born just four years before the foundation of the Town's College of Edinburgh in 1582. It matters little whether credence is to be given to the detailed, but apparently mythical, story of Bower in his history of Edinburgh University, when he tells how Bishop Reid of Orkney bequeathed 8,000 merks "to the town of Edinburgh for the purpose of erecting a University within the city," and that in 1561, "on the faith of speedily obtaining" the said sum, the town council discussed the establishment of a college, and "in 1563 purchased part of the ground upon which the College at present stands"; and that "three years afterwards the unfortunate and susceptible Mary, whose generosity was unbounded, her love of learning sincere, and her proficiency considerable, entered warmly into the same views, and endowed with revenues the institution which she was so anxious to patronize." Certain it is that about the date indicated the town council began to busy themselves regarding the application of public moneys which hitherto had been paid to "papists, priests, friars, monks, nuns, and others of that wicked sort, for maintaining of idolatry and vain superstition," and resolved that these should "be applied to more profitable and godly uses, such as for sustaining of the true Ministers of God's Word, founding and building of Hospitals for the poor, and Colleges for learning and upbringing of the youth, and other such godly works."

Gradually from out the rather vague educational proposals the conception of the Town's College took shape. The city register, of date August 9th, 1564, records that the stonework of the Kirk-of-Field is being taken down, and that the council think it should "be bought for the good Town, either for the Hospital or for a University to be made in the said Kirk-of-Field."

The final acquisition of the Kirk-of-Field took time. There seems no indication that Mary Stuart was inspired by a wish to transfer the site for the purpose. The desire of the city of Edinburgh and the city ministers to have a college founded seems to have been thwarted in part by the three older universities in which the influence of the bishops continued. It seems certain that the final practical move towards the foundation of the college was made by the city ministers, more especially Mr. James Lawson, who, according to Craufurd, "Having obtained a gift of a University within the City, in the beginning of this year (1581) purchased from John Gib and John Fenton, servants

to the King, their right to the Kirk-of-Field to be a place for the situation of the intended College."

Whether or not there was an earlier charter, as has been suggested, the charter of James VI, dated April 14th, 1582, gave large powers to the town council in the direction of founding a college or colleges. It is significant in this connexion that in 1617 King James VI—or, as he then was, King James I of England—when he revisited Scotland, is reported to have said: "After the founding of the college of Edinburgh had been stopped for sundry years in my minority, so soon as I came to any knowledge I zealously held hand to it."

However we may choose to appraise the amount of King James's zeal, the above statement made by the King has especial interest in view of his having lived in Edinburgh during twenty-one years following the grant of the charter to the university, and thereafter in England some fourteen years before the above statement was made. Coming as the statement does some thirty-five years after the event, it suggests that the circumstances of the grant of the charter had made a definite impression, and there is reasonable presumption that the King was familiar with subsequent developments during his residence both in Edinburgh and later in the South. At that time there was no question regarding medical teaching in Edinburgh.

To return to Harvey. By his own qualities and happy matrimonial alliance his advance was rapid, professionally and socially. Four or five years after his return from Padua we find him a Fellow of the College of Physicians and physician to St. Bartholomew's Hospital, being supported for the latter office by King James and by the president of the Royal College of Physicians. During the succeeding years his relations with the Court had become pretty intimate. This is evidenced by the manner in which his appointment as Physician Extraordinary was made. Harvey was thus in close touch with King James at the date when the King recalled, in the words I have quoted, the circumstances of the foundation of Edinburgh University. So rapid was Harvey's advance in the College of Physicians that in 1613 he was appointed one of the four Censors of the College, and, in 1615, Lumleian Lecturer.

#### THE ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

It is not likely that those facts and their bearings were unknown to King James. Can we doubt that from time to time conversation turned on such topics? It is, therefore, of very great interest to recall that the first move towards the foundation of the Royal College of Physicians of Edinburgh was made in 1617, on the occasion of the King's revisit to Holyrood. If nothing immediate came of it, it seems hardly conceivable that the endeavour failed from lack of interest on the part of the King.

The personal relations between the Court and Harvey were continued throughout the reign of Charles I, who nominated him to more than one office, and, in 1631, appointed him to be his Physician in Ordinary. It is significant to recall that that date corresponds very nearly with a further effort towards the foundation of the Edinburgh College. Harvey was by this time in intimate relations with King Charles, and accompanied him to Holyrood in 1633. On the occasion of that visit Harvey, who found time to study the solar geese on the Bass Rock, cannot fail to have become well versed in the *pros* and *cons* in the leading professional question of the moment. At that date—within a few years after the publication of his great work on the circulation—his interest in the project and his influence must both have been great. They were not, however, sufficient to overcome local prejudice and animosity.

From now onwards Harvey's life was growingly overshadowed by the surging difficulties which led finally to civil war and the execution of the King in 1649. But during the Oxford period (1642-46) began the very significant relation between Harvey and Scarborough which ultimately ripened into affectionate friendship. In a very literal sense Harvey's mantle fell on Scarborough (see the terms of Harvey's will), who went to London on Harvey's suggestion, and succeeded him as Lumleian Lecturer in 1656.

During ten or twelve years these two men must have exchanged many ideas. Inevitably they would discuss

medical and academical matters. Can it be supposed that Harvey knew the facts both from conversations with the King and by personal observations in the city itself. The proposals for the establishment of a College of Physicians can hardly have been excluded from Harvey's talks with Scarborough.

It is a fact of pathetic interest that the next serious move towards the foundation of the College of Physicians of Edinburgh occurred in 1657—the year of Harvey's death. The proposal had the sanction of the Protector, and would probably have been carried through but for Cromwell's death the following year. Between that date (1657) and the actual granting of the Charter to the College (1681) there was an interval of twenty-four years. During that period various forces and counter-forces were at work until all the difficulties were removed.

Edinburgh would seem to have had a renaissance of intellectual activity and culture. This was evidenced in the trend of young Scotsmen about 1660 towards the universities of Holland, France, and Italy. Of those who ultimately constituted the first twenty-one Fellows of the College of Physicians, approximately one-half went abroad for study—the majority to the University of Leyden, where later, in 1692, one of the first Fellows of the College—Archibald Pitcairne—became professor of medicine and was probably one of the teachers of the great Boerhaave. Those are significant points in relation to the final successful effort to found the Royal College. Presently a band of keen, zealous friends began to hold fortnightly meetings (conferences) in Robert Sibbald's house. Chief among these were Doctors Balfour, Burnet, Pitcairne, Sibbald, and Stevenson.

#### SIR CHARLES SCARBOROUGH AND THE COLLEGE.

The appointment of Prince James, Duke of York, as High Commissioner to Scotland brought the Prince to Holyrood in 1679. In his train, as medical attendant, came Sir Charles Scarborough, who, in succession to Harvey, had become Physician to the King. The quickened intellectual atmosphere would prove congenial and interesting to Scarborough, who by this time was a member of Council of the Royal College of Physicians of London. Balfour he had already known as a pupil of Harvey. Towards Pitcairne he must have been drawn especially, for which later, both in Edinburgh and Leyden, he did much to disseminate. Sibbald, speaking of the Holyrood group, says: "We consulted with Sir Charles, and found him our great friend, and very ready to give us his best assistance, with the King and the Duke, who was by this time High Commissioner." Sibbald was successful in persuading the Earl of Perth and his brother to be friends to the enterprise, and he says, "they brought over many of the nobility to favour the design." To this happy combination of circumstances must be added a piece of good fortune that came to Sibbald, who relates it as follows:

"I having recovered one warrant of King James the Sixth of happy memorie [obtained by his uncle Dr. George Sibbald and left in his care], directed to the Commissioner and Estates of Parliament then sitting in Scotland, dated the 3rd July 1621, with an reference by the Parliament thereunto, to the Lords of Secret Counsell with power to doe therein what they thought fit and that their determination therein should have the form of an Act of Parliament, dated the Second of August 1621, produced this to his Royal Highness, who, as soon as he saw it superscribed by King James, said with much satisfaction 'he knew his grandfather's hand and he would see our business done,' and from that moment acted vigorously for us."

After unavoidable discussions as to its form, the completed Charter was duly written on parchment and the Great Seal was appended on St. Andrew's Day, November 29th, 1681.

The College is fortunate in having in its possession an engraving of Sir Charles Scarborough, who thus played so important a part in relation to its foundation. But I may be permitted to express regret that the original oil painting of the eminent benefactor, which was presented three or four years ago to the Royal College of Physicians of London, did not come to this hall. During the past year the College has had the good fortune to receive at the hands of one of its Fellows, Dr. Alexander Blackhall-Morison, an early portrait in oils of William Harvey

himself, whose relations—direct and indirect—to the foundation of the College can no longer be overlooked.

The commemoration of the bicentenary of the Medical Faculty of the University of Edinburgh during the present year has rekindled interest in the history of the medical school. At those celebrations becoming tribute was paid from many sides to the supreme part played by the first Fellows of the Royal College of Physicians in the establishment of the Faculty of Medicine within the University. Four years after the granting of the Royal Charter the College of Physicians submitted a petition for the establishment of professorships of medicine; and in 1685 the town council of Edinburgh appointed Sir Robert Sibbald, Dr. James Halket, and Dr. Archibald Pitcairne to be professors of medicine within the University.

This first gesture, culminating as it did in the creation, in 1726, of the Faculty of Medicine, was fitting crown of the renaissance of intellectual activity in relation to medicine which emerged in Scotland after the union of the two kingdoms. It follows that whatever links may be suggested as attaching William Harvey to the Royal College of Physicians must, by the rules which govern lineal relationship, be regarded as attaching him no less surely to the Medical Faculty of the University. So far as my memory serves, during the recent bicentenary celebration of the Faculty, no suggestion of so significant a connexion emerged. I trust my fellow Harveians will not think me presumptuous in thus endeavouring to repair the omission.

#### THE HARVEIAN SOCIETY OF EDINBURGH.

There remains little time to dwell on another line of thought which I should gladly have developed in more immediate relation to our Harveian Society.

Alongside Harvey's pre-eminent genius as observer and interpreter of nature, there was a rich store of human qualities which attached him to his friends and fellows, and continues to arouse feelings of personal regard and affection. In making over to his beloved College his paternal estate at Burmarsh in Kent, with provision for a salary to the College librarian, and the endowment of an annual oration, he begged that the orator should exhort the Fellows of the College "to search out and study the secrets of nature by way of experiment, and also for the honour of the profession to continue mutual love and affection among themselves." It was the dual character of Harvey's manhood—his science, on the one hand, and his humanity on the other—which led to the establishment of our own Harveian Society and the Harveian Festival which, for the 139th time, we are holding to-night.

The objects of the Harveian Society, as primarily indicated, were threefold—namely, to commemorate the discovery of the circulation of the blood, to cherish a kindly feeling among the members of the medical profession, and to foster a spirit of experimental inquiry among the students at this school of medicine.

The third object of the society, embodied in the award of an annual prize to the author of the best essay on a subject announced by the society, has fallen into abeyance, and the laws read now as follows:

**Law II.**—The Objects of the Society shall be to commemorate the discovery of the Circulation of the Blood, and to cherish a kindly feeling among the Members of the Medical Profession.

**Law III.**—The Society shall endeavour to accomplish these objects by dining together annually on April 12th, the birthday of the illustrious Harvey; and in any other way the Society shall see fit.

To-night, in commemorating the discovery of the circulation of the blood, as enjoined by the laws, we do reverently place anew our wreath of laurel before the monument of Harvey. It was long the practice of the society to dine on the anniversary of his birthday. The changes which have inevitably occurred in relation to the school of medicine—the division of the session into terms with alternating holidays—have rendered the month of April unsuitable for a commemorative gathering. Hence it comes—that, in place of dining together on April 12th, the birthday to-day (July 2nd, 1926).

If the primary purpose of the Harveian Festival is to pay reverent homage to William Harvey, it is certain that

it was no less the purpose of its founders to cherish a kindly feeling among the members of the medical profession.

The Harveian Society was a direct offshoot from the older Aesculapian Club. Both were founded by Dr. Andrew Duncan, and both have flourished—and flourished abundantly—to the present time; nor is there indication of senility or decay.

The Aesculapian Club was established in 1773, and consisted exclusively—as it does at the present day—of Fellows of the Royal College of Physicians and Fellows of the Royal College of Surgeons. The Aesculapian Club, which was essentially a supping, or dining, club, was limited not only in numbers (ranging from 12 to 22 members in all), but also in funds. When, three years after its foundation, the members of the Aesculapian Club proposed to widen their interest and influence by presenting a prize for medical investigation, they found—canny Scots—that, by reason of the limited number of members, the presentation of the prize (although amounting only to some 5 guineas) would press heavily on the purses of its members. Accordingly, the proposition was made that, without infringing on the prestige of the select Aesculapians, a larger society should be instituted which would include not only Fellows of the Colleges but graduates of the University and men in practice in the counties adjacent to Edinburgh or attached to the naval and military services.

Thus our society had its birth in 1782—bearing apparently two baptismal names by which it was known indifferently—namely, the Harveian Society, or the Circulation Club. Judging by available documents it would seem at the beginning to have been more commonly known as the Circulation Club.

The initial roll of the club (1782) contained 23 names, including, of course, that of its founder, Dr. Andrew Duncan, whose portrait by Raeburn adorns the College hall, and, it is interesting to note, Dr. Nathaniel Spens, whose portrait by Raeburn in the dress of the King's Body Guard for Scotland is well known to you, Mr. Benjamin Bell, Dr. Alexander Monro, Dr. Daniel Rutherford, and others which recall far-reaching connexions with the medical history of Edinburgh. The first president was very naturally Dr. Andrew Duncan, who thereafter assumed the office of secretary, which he held for forty-six years to the end of his life.

One sometimes thinks with envy—too hastily perhaps—of the leisure times which the profession enjoyed 150 years ago. Yet Andrew Duncan—immersed in practice, lecturing on the principles and practice of medicine, first outside and latterly within the University, founder and moving spirit of the Aesculapian, Harveian, and Gymnastic Clubs, institutor of the *Edinburgh Medical Journal*, and inspiring influence of the Royal Edinburgh Asylum, Royal Public Dispensary, and Scottish Horticultural Society—must have been not only busy, but possessed of superabounding health and energy.

How the Harveians of those days realized their purpose to “cherish a kindly feeling among members of the profession” may perhaps best be realized by two pictures drawn from the minutes of the society—both relating to Harveian Festivals held at a time when Great Britain was overshadowed by the fateful possibilities of the Napoleonic wars.

The first picture is from the Harveian anniversary of April 12th, 1815—less than two months prior to the battle of Waterloo, when Dr. Andrew Duncan, the septuagenarian secretary, was promoted to the degree of Doctor of Mirth and Social Glee. It is best described in the quaint phrasing of the bard of the society:

A Motion was made,  
And all present were glad,  
As our joys are so few, and our time is so fleeting,  
That our vacancy in the chair, of Doctor of Mirth,  
Should be regularly fill'd up at our next meeting.

So for this situation,  
Without hesitation,  
As the time was so precious, the Preses did name  
Our trust-worthy Secretary, who, for humour and pleasantry,  
through full half a century had acquired much fame.

Then next it was mov'd  
And most highly approv'd  
That the President, mentioning the candidate's qualities,  
Should prepare his diplom; and, when next in this room  
have him duly invested with all the formalities.

Yet, stop, say some, What's all the hurry,  
Who is the hero of your story?  
Who is the man that's done such wonders,  
And thus has benefited hundreds  
Of generations yet to come,  
Of countless myriads a vast sum?  
I answer, neither Jew nor Turk  
E'er had a hand in this great work;  
And joy must gladden in your faces  
And national pride add to its graces,  
When I inform you that the man  
Who's thus completed Harvey's plan  
Is one that's here; for him I claim  
Th' immortal fame, and now do name  
Andrew Duncan, virum gravem,  
Moribus et vultu suavem,  
Virum septuaginto annorum,  
Dictum vulgo seniore,  
Sed abhinc to be styl'd majorem,  
Because in mirth far juniorem  
Than half the youngers now before him.

The Diploma was couched in the following terms:

DIPLOMA.  
*Sodalitas Edinburgensium filiorum Aesculapii,  
In GULIELMI HARVEI honorem instituta,  
Ut in aeternum floreat inventum utilissimum,  
Circulatio sanguinis,  
Omnibus ad quos haec pervenerint  
Salutem.*

With all the rights of due decorum  
Nunc in altissimum honorem,  
Erectus sit Andreas Duncan,  
Honestus vir, si talis unquam.  
As to know him is to respect him,  
So nos habemus michi delectum,  
Quod fausto tempore et loco  
Cum risu, cantilena, joco,  
He has, auspiciis Minervae,  
Completed the great plan of Harvey;  
Proving that sanguinem abire  
A corde et ad cor redire,  
And ita, rite, circumire,  
By keeping heartsome, light and cheery.  
So therefore “cum nunc creamus,  
Statuimus et proclamamus,  
Of mirth Magistrum et Doctorem,  
Vel si libet Professorem.”  
And farther, nos auctoritate,  
Invest him plena potestate,  
“Quando liberit, potandi,  
Ludendi porro et jocandi,  
Moestos vino medicandi,  
Et ad risum fabulandi.”

The diploma, held in the hand, was delivered in pronouncing the last words of the following address:

Senex venerande, magnopere laudando  
Propter innatam tuam amoenitatem,  
Et propter virtutem minime hirsutam,  
Cui, vita bene acta, senectus est facta,  
Vere jucunda.  
Doctrina ornate, honore onerate,  
Probis probate, omniū grato.  
Qualicumque aetate.  
Accipe honorem, valde decorum,  
Minime quem volumus, attamen quem possumus  
Tibi donare.  
Quo, tardus et serus abiens in coelos  
Vivens hic, beate, bene, fortunato,  
Laete, quiete, placide, complete,  
Longum fruar.

The second picture is from the Harveian anniversary of April 12th, 1812, when the degree of Doctor of Merriment was unanimously conferred on the Rev. Dr. William Moodie, Minister of St. Andrew's parish church and professor of Oriental languages in the University, who, sadly enough, died within a few months of his promotion to the said degree. With glasses duly charged, the feelings of the Harveians towards their Pontifex Maximus are thus expressed:

To all good fellows be it notum,  
That William Moodie, Virum Scotum,  
Has proved his power in merriment,  
Ut scripta multa nunc nos docent;  
And to reward his sterling wit,  
Quod felix nunc faustumque sit,  
Doctor of Mirth, nos hunc creamus,  
And to all laughers, commendamus,  
In proof of which his health we drink,  
Wishing him well, et nunc et hinc.

The Pontifex Maximus, having duly received this diploma, sent the following acknowledgement to the secretary:

With Aesculapians I did sup,  
And with Harveians kept it up,  
With dear Gymnastics oft was happy,  
Our friends were kind, our liquor nappy,  
And he who now the truth can tell,  
Ne'er saw wa'r 'mang them than himself.

# ACUTE NODULAR LEPROSY ORIGINATING IN THIS COUNTRY AND CURED BY VACCINE TREATMENT.

BY

E. GRAHAM LITTLE, M.D., F.R.C.P. LOND., M.P.,

PHYSICIAN FOR DISEASES OF THE SKIN AND LECTURER ON DERMATOLOGY, ST. MARY'S HOSPITAL, LONDON.

(With Special Plate.)

Mr. X., a Chinese student, aged 36, who had been six months in this country, was brought to me on May 14th by Dr. Sherwill Dawe, with the following remarkable history:

The patient had been under his care for some weeks, suffering from severe pain in the left arm from the axilla to the wrist. Local applications, but no medicine, were given until three weeks later, when an eruption of nodules came out quite suddenly upon the face, and later upon the body. These gave rise to no subjective symptoms; there was no itching or pain. Under the impression that the eruption was an urticaria, calcium lactate was given by the mouth, and no other medicine had been taken by the patient. The eruption spread rapidly over the trunk and hands, and a patch of infiltrated skin, approximately four inches by two inches, appeared near the wrist, and a similar patch of induration upon the back a little later. He was brought to see me ten days after the first onset of the rash. The photograph (Fig. 1) gives a very fair impression of the state of the face when I saw him on May 14th. The skin over the forehead and cheeks was studded with granulomatous nodules; the face was generally swollen, especially over the forehead and nose. A large number of granulomatous nodules and plaques of indurated reddened skin were also found upon the back and front of the trunk. Upon the left forearm there was a very prominent induration of the skin, with a typical dusky flush; the ulnar nerve upon this side was greatly swollen and tender. The patient was obviously acutely ill, but no rise of temperature had been noted. The glands were generally enlarged.

I told Dr. Sherwill Dawe that I regarded the eruption as a lepride, and I obtained his permission to show the patient at the meeting of the Dermatological Section of the Royal Society of Medicine on May 20th. My diagnosis was confirmed by the unanimous opinion of the members present.

In the discussion which followed, Dr. Sequeira mentioned a case with an acute outbreak—the only one in his experience—in a woman who came from South Africa. Dr. Macleod gave an instance under his care of a boy in whom an acute outbreak of nodules, practically covering the body within forty-eight hours, had occurred, but the patient had had a previous attack of leprosy two years before. Dr. Whitfield mentioned a case under Dr. Pringle in whom an acute leprosy swelling of the face had come on within a few hours of an attack of malaria. Dr. Adamson pointed out the analogy between these cases and post-exanthematous lupus, which occurred after measles or other fevers in children who suffered from tuberculous glands. The rarity of such acute cases may be gauged from the fact that four medical men, with vast experience of skin disease, could each cite only one instance within their individual observation.

Further discussion ensued upon the measures to be taken, and it was again the unanimous opinion of the meeting that the prognosis was so desperate that the patient should be urged to take immediate steps to return to his home in China, if arrangements could be made for his transit.

Leprosy is not a notifiable disease in this country, and there is no adequate provision for the reception of such cases. Some years ago one of the members of the Section was confronted with an extremely difficult position, in which he sought the advice and assistance of his colleagues. A man suffering from leprosy had been living in lodgings in London. A lawsuit for damages, brought by the landlord, appeared probable, and this lesson of the very serious plight of a patient suffering from leprosy in England added to the urgency of the advice which I gave to Dr. Dawe, that the patient should leave England as speedily as possible, before his condition would prevent him from doing so.

Now comes the remarkable sequel. Mr. X. had the good fortune to come under the observation and treatment of Dr. James Hasson, whose very extensive experience of leprosy in Egypt enabled him to give a much more promising prognosis. The treatment adopted by Dr. Hasson is appended in a communication for which he is solely responsible.

The opportunities for seeing leprosy in this country are necessarily very limited, but I have had some exceptional opportunities of observing the disease in South Africa, the West Indies, and the Canary Islands. Some fifteen years ago I had the privilege of watching a case of leprosy under treatment by my colleague Sir Almoth Wright, who was giving small intramuscular doses of an emulsion of leprosy tissue obtained from a tumour excised from the patient. Some improvement at first resulted from this treatment, but it was never very encouraging, and was abandoned. Several other attempts have been made with the same means, notably by Dr. Winkelried Williams, but the improvement has not been such as to recommend a wide adoption of the method. It is the general experience that the products of chaulmoogra oil have not fulfilled the hopes expressed by Sir Leonard Rogers in his Croonian lectures of 1924.

The astonishing results obtained in the case now under consideration can best be apprehended by comparing Fig. 2, after treatment, with Figs. 1 and 3, before treatment. I examined Mr. X. in October, and am happy to report that the nodules and the tumefaction of the skin of the face have completely disappeared, the nodules leaving no trace of their presence other than a slight deepening of pigmentation. The indurated plaques upon the back and forearm have also vanished, leaving only a deepening of pigmentation in the flaccid skin covering the site of the induration. The general health of the patient has improved beyond all recognition, and it would really seem that we have at last obtained an effective method of treatment of this dreadful disease.

## COMMUNICATION BY DR. JAMES HASSON.

The patient mentioned by my colleague Dr. Graham Little was sent to me by Dr. Manson-Bahr last June. I have nothing to add to the above account of the patient, except that there was a specific rhinitis which made breathing difficult. His temperature was one degree below normal, and the large lepride of the forearm was in certain parts anaesthetic, and in other parts hypo-aesthetic.

I commenced vaccine treatment immediately, and after a series of injections of 23 ampoules, a majority of which were given into the veins, the lepromata described above, as well as the large infiltrated lepride, melted away.

I showed the patient to Dr. Manson-Bahr after this series of injections, and we agreed to let the patient have a rest of one month, during which time I gave him one or two injections a week of 2 per cent. solution of lecithin in olive oil, inasmuch as his urine contained an appreciable quantity of phosphates. He lost a stone in weight.

The vaccine injections were resumed about July 20th—four a week, then three a week, and finally two a week—in very small doses so as to avoid the strong reaction from higher doses.

The patient has had fifty-three injections in all of vaccine in small doses, after a special formula containing three milliards of Hansen's bacilli instead of five, and five milliards of *Bacillus pyocyaneus* instead of fifteen, in each ampoule—an alteration, as explained above, determined by the general health of the patient.

The present situation is as follows: All the lepromata of the face and the body have completely disappeared; the large lepride of the forearm has gone. The rhinitis is cured to such a degree that the patient breathes normally. The nasal septum is intact and there is no indication of destruction of the bones of the nose. The anaesthesia of the lepromata and of the lepride gave place during the first week of treatment to hypo-aesthesia. Both these symptoms have disappeared now and the hair is growing normally. Blistering of an old nodule shows in the blisters complete absence of Hansen's bacillus. The

method of preparing vaccine has been described in the *Transactions of the Royal Society of Tropical Medicine and Hygiene*, No. 7, vol. xix.

By means of a stick of carbonic acid snow applied for from a half to one minute upon the lepromata or upon the anaesthetic macules a blister results, which if emptied twenty-four hours later contains a large number of the bacilli of Hansen. This method may also be used to confirm or to contradict the diagnosis of leprosy when it is doubtful.

The preparation of the leprosy vaccine is a very delicate process, and necessitates a long practice. When the blisters are formed on the patients with the CO<sub>2</sub> snow they must not be emptied until after a lapse of twenty-four hours. Thirty-six hours are necessary if it is desired to obtain a fair number of Hansen's bacilli. The serum taken from one patient with one special form of Hansen's

disease is then mixed with the serum taken from other patients, suffering from different forms of leprosy, and the whole mixture is kept in the incubator for from fifty days to three months at 36° C. Then a mixed culture of *Bacillus pyocyaneus* is added to the serum containing the Hansen's bacilli (previously rendered incoagulable by the addition of a sterile solution of 2½ per cent. sodium citrate). The whole is transferred to the centrifuge for twenty minutes, the requisite quantity of distilled water is added to the solution, the bacilli are counted, then washed with petrol-ether, and the vaccine put up in 2 c.cm. ampoules. An ampoule of 2 c.cm. contains five milliards of Hansen's bacilli and fifteen milliards of *Bacillus pyocyaneus*.

The conditions vary for each case according to the general state of the patient; but the average dose is two ampoules, to be injected into the veins weekly.

### PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, NOTTINGHAM, 1926.

#### SECTION OF NEUROLOGY AND PSYCHOLOGY.

E. FARQUHAR BUZZARD, M.D., F.R.C.P., President.

#### DISCUSSION ON PITUITARY DISORDERS.

##### OPENING PAPERS.

I.—GORDON HOLMES, C.M.G., C.B.E., M.D., F.R.C.P.,

Physician, Charing Cross Hospital; Physician, National Hospital, Queen Square, W.C.

My aim in opening this discussion will be to give a general survey of pituitary disorders and leave it to those who follow me to fill in details. I am fully conscious of the difficulty of the task, for the hypophysis, or pituitary body, is a complex structure composed of several distinct parts of different origin and different function, and disease may involve all of these parts together, or any one or more of them at a time; again, it may produce either loss or excess of function. Further, recent investigations have thrown doubt on hypotheses which we have accepted as physiological facts; it may, indeed, be said that the physiology of the pituitary body is still in the melting-pot. Another difficulty in the subject is that whatever may be the normal functions of the hypophysis they are so closely related to the activities of other glands, and especially to those of the sex organs, that a distinction of the clinical symptoms produced by their disease is often not easy, or their interpretation is uncertain.

It will, however, be my aim to deal with the clinical manifestations only of pituitary disease, and to place before you mainly the practical applications of my own experience. I shall have to refer from time to time to recent experimental work, but I shall do so only when this is necessary for the recognition and treatment of pituitary disorders.

It is now generally admitted that the pituitary body has important influences on growth, on sexual development and activity, and on the general metabolism of the body, and that these separate functions depend on different parts of it. A secretion or hormone of cells of the anterior lobe stimulates the growth of bones and influences the development of the skin and of some visceral organs; the pars intermedia and the posterior lobe control the development of the sex organs, while carbohydrate-metabolism is also influenced by the posterior lobe. The infundibulum, or rather the pars tuberalis that lies on it, is probably concerned with the secretion of urine.

The functions of the pituitary may be disturbed by many different types of disease. Tumours arising from its cells are probably the most common lesion in clinical practice, but it may be invaded by metastatic growths too. Then

it may be injured by disease originating outside the sella turcica, as by tumours growing from the meninges or from Rathke's pouch; by the distended floor of the third ventricle in the case of hydrocephalus; or by syphilis or encephalitis in the region of the infundibulum. These extrasellar lesions may compress the gland, or produce effects by blocking the secretions from the posterior lobe that normally enter the cerebro-spinal circulation through the third ventricle, or interrupt the nervous connexions between the pituitary and the hypothalamus. In other cases there is an aplasia or defective development of the pituitary, owing to either congenital or mechanical causes, or the organ may undergo regressive changes. Finally, alterations in the size and functions of the pituitary may be associated with disease or functional disturbances of other endocrine organs, as in pregnancy, in castration or atrophy of the sex glands, and with disease of the thyroid.

The clinical symptoms of pituitary disease are generally divided into those due to overactivity of a part of the gland, producing the condition of hyperpituitarism, and those that result from loss or deficiency of some of its secretions, or hypopituitarism. This classification is probably the most useful that can be proposed in the present state of our knowledge. It is, however, as yet an unproved assumption that the secretions of the cells of an adenoma are identical with those of normal cells, and the gross pathological lesions that most commonly cause symptoms can scarcely have selective actions on one part of the gland only. Adenomata of the anterior lobe, for instance, necessarily compress other parts in addition to altering the functional state of the anterior lobe cells. Many clinical symptoms must therefore be regarded as those of a dyspituitarism or altered cellular function, or as the combined result of the abolition or defective activity of some cells or parts, and the overactivity of other cells or parts. For clinical purposes, however, it is still advisable to retain the terms "hyperpituitarism" and "hypopituitarism."

The best method of presenting the subject for discussion will probably be to describe to you some of the more important clinical features of pituitary disease, and the more common modes in which they are grouped together.

##### DISTURBANCES OF GROWTH.

The best known and most common form of pathological overgrowth is acromegaly, which, since Marie described it in 1886, has been known to be associated with an enlargement or a tumour of the anterior lobe of the pituitary. It is true that in a few of the recorded cases no tumour or other lesion of the hypophysis was found, but in these there may have been a similar growth or an overfunction of an accessory pituitary, the common presence of which in the neighbourhood of the main gland or along the course of the pharyngo-cranial canal has been pointed out by Erdheim and others.

Benda originally showed that the characteristic lesion in acromegaly is an adenoma of the eosinophil cells of the anterior lobe, which usually deviates so little from the structure of the normal elements that we may assume the tumour produces a similar secretion; in other words, there is a physiological excess as well as an anatomical increase

of these elements. Dott and Bailey, in their recent study of hypophyseal adenomata, have come to the same conclusion.

As a direct result of the excessive secretion, or possibly as a result of it combined with changes in the activities of other ductless glands, an overgrowth of certain tissues of the body occurs. The most prominent increase in size is in the skeleton, leading to the characteristic changes in the face, jaw, and skull, as well as in the spine and in the distal segments of the extremities. The malar bones become prominent, the supraorbital ridges bulge owing to increase in size of the frontal sinuses, and the lower jaw enlarges, producing frequently a prognathism with the lower teeth projecting beyond the upper. Frequently the teeth of the mandible are separated widely, since they do not enlarge as the bone in which they are embedded.

The chief changes in the skull are an increase in bulk of the natural ridges and points of attachment of the muscles, but the common complaint that the patient requires larger hats as the disease progresses is in some cases due to a general increase in the size of the head. The chief vertebral change is the development of a diffuse upper dorsal kyphosis, but it is sometimes represented only by an unnatural prominence of the upper dorsal spines. Radiographic examination of the bones of the limbs generally reveals less change than might be expected, but the phalanges are often enlarged and exostoses on them are common.

It is to a thickening of the soft parts, especially of the dermis and subcutaneous tissues, that much of the deformity is due; the skin becomes thick and inelastic, and is usually so adherent to the tissues beneath it that it cannot be raised or pinched up in folds as in normal persons. This adds to the characteristic coarseness of the face, and gives the fingers their sausage-like or cylindrical appearance. Other soft organs enlarge too: the nose is generally large, coarse, and broad, the lips thick, and the tongue so massive that it seems to fill the whole mouth; the ears also increase in size. The visceral organs may also enlarge; a hypertrophy of the heart has been described, as well as enlargement of the liver, spleen, pancreas, and kidneys, but these changes have little or no clinical or pathological significance. In one case, on which I made a *post-mortem* examination, the walls of the intestines were considerably thickened, while the colon was enormously enlarged, its lumen being two or three times as great as the normal. This may be the explanation of a symptom I have seen in a few patients with acromegaly; they complain of severe constipation, but periodically pass motions of enormous size, probably because the intestinal contents accumulate in the enlarged bowel. Many of these patients have also excessive appetites.

#### *Gigantism.*

The acromegalic is characterized by overgrowth of certain portions of the skeleton leading to abnormal proportions, but in subjects who develop disease of the pituitary in early life a general increase in height and bulk may be the most prominent feature. Frequently growth in these cases continues beyond the usual period of adolescence. In the giant the normal proportions of the body are retained, or more commonly the limbs are abnormally long but well shaped. There are, however, often anomalies: the sex glands are sometimes underdeveloped and the secondary sexual characters poorly marked. There are many conditions that predispose to gigantism: some subjects are probably normal in every respect and mere "sports"; in others the excessive growth is connected with lesions of other glands, and especially the sex organs—among eunuchs, for instance, abnormal stature is not uncommon.

In some giants, however, the pituitary is undoubtedly at fault, a hyperplasia or adenoma of the anterior lobe, or possibly only a functional overactivity, providing the stimulus to skeletal overgrowth; but this is possible only before the epiphyses have permanently fused. There is now experimental evidence, too, that the anterior lobe of the hypophysis has an influence on growth, for Uhlenhuth has shown that tadpoles fed on it increase in size more rapidly and to a greater degree than controls, and Evans and Long have obtained similar results in rats by the intraperitoneal injection of fresh gland substance. The

abnormally great stature sometimes seen in eunuchs and among the Russian Skoptzen, who in early life submit to castration, may be related to hypophyseal activity, for an increase in size of the anterior lobe, and presumably therefore increased function, is known to follow removal of the testes or ovaries.

The view that gigantism is acromegaly in early life cannot be accepted, as true acromegaly has been described even in childhood. There are, however, close relations between gigantism and acromegaly. Many giants develop symptoms of acromegaly in later life, and it is not unusual to find acromegaly appearing in persons of large build, even though they cannot be described as giants. Again, similar regressive changes occur in the two conditions; both the acromegalic and giant are usually at first strong muscular persons, but in both a progressive weakness; surprising in view of the size of their bodies, is liable to develop, and may progress to a final cachexia. In both, too, the sexual functions are depressed or in abeyance, and both frequently show the same apathy, indolence, lack of energy and interest, and narrowing of emotional life, though the giant is usually more infantile in his mental outlook.

#### *Dwarfism and Infantilism.*

Experimental observations have shown that injury or partial removal of the anterior lobe may, in young animals, lead to a lack of physical development, and clinical observations leave no doubt that disease of it in children or early adolescence may result in dwarfism, or an arrest of development with conservation of the normal adult proportions; or, on the other hand, to infantilism, in which growth is not necessarily stunted, but the morphological characters of infancy and an absence of sexual development persist beyond the age of puberty.

True pituitary dwarfism is not common, but I have had two cases under my care. Both were simply men in miniature, with fairly developed genitals and normal hair growth. In both the symptoms started in late childhood, and the associated features suggested suprapituitary growths; in one the shadow of a calcified tumour was present in radiograms of this region, and he became blind, the loss of vision extending from the temporal halves of the visual fields. In other cases the dwarfism is due to congenital absence of the hypophysis, as in the patient recorded by Peritz, or to its atrophy. One interesting feature of these cases is that, usually in the third decade of life, they become as it were prematurely senile; they lose weight, their skin becomes thin, dry, and wrinkled, and they may grow either bald or grey.

Infantilism is more commonly seen; here the stature is not necessarily short, but the general development is slender. The striking feature is the childlike configuration of the body, the infantile state of the sexual organs, and the non-development of secondary sexual characters, and usually an unbroken high-pitched voice. Obesity is a prominent feature of many of these cases, but this will be dealt with later.

#### *Adiposity.*

Cushing and others have shown that experimental damage of the pituitary, and especially lesions of the posterior lobe, may lead to the deposition of an abnormal amount of fat in the subcutaneous tissues as well as in the visceral organs. A similar adiposity is a frequent accompaniment of pituitary disease, no matter what its nature or the origin may be, provided it injures the posterior lobe; it is sometimes seen in acromegaly, in certain cases of gigantism, and in dwarfs, but it appears most characteristically in the state to which Fröhlich has given the name "dystrophia adiposo-genitalis." In addition to primary hypophyseal disease it may be produced by any lesion that interferes with the functions of the pituitary, as suprasellar tumours, chronic hydrocephalus with distension of the floor of the third ventricle, and syphilitic basal meningitis, especially congenital infection. Cushing originally attributed it to defect of the posterior lobe, and certain clinical observations point to the same conclusion; recent work, however, suggests that it may not be the direct effect of the pituitary lesion, but results from damage of adjoining centres in the base of the brain, or from the genital atrophy that usually accompanies

hypophyseal disease. The resemblance to the obesity in eunuchs is certainly striking. Another argument in favour of the latter hypothesis is the case of a patient with hypopituitarism recently under my care, who had increased 4 st. in weight in six months, but lost most of his abnormal fat after a testicular graft. Peritz has published a similar observation in a hypophyseal dwarf.

The distribution of the fat is not in itself pathognomonic of pituitary disease; a similar adiposity results from genital defects and other pathological conditions, and occurs normally, particularly in families which incline to obesity. In the most common type the fat is laid down mainly on the breasts, abdomen, buttocks, the upper portions of the thighs, and over the pubis; but in other patients the increase is found chiefly in the lower limbs above the ankles, the trunk and the upper extremities being more or less free. Sometimes, however, there is a general adiposity.

#### Skin.

More or less characteristic changes in the skin usually accompany the obesity, but they occur also in the non-obese cases in which atrophy or non-development of the genital organs is the chief feature. It is usually soft, thin, and smooth, often practically hairless, and as a rule dry, though rarely scaly. The folds over joints and other regions may be obliterated, and to the touch it has the soft velvety feeling of childhood. In younger patients its colour is generally good, though many are anaemic, but in middle life it becomes thin and wrinkled, resembling the skin of old age. In acromegaly and other conditions associated with overactivity of the anterior lobe it is, on the contrary, thickened, firm, and rough, and often deformed by warts and small tumours of the fibroma molluscum type.

Simmonds has described an interesting condition, under the title "hypophyseal cachexia," which resembles in many respects the condition described in animals by Cushing and others after total removal of the pituitary. It results from a rapid destruction of the whole hypophysis, which in some of the published cases was due to extension of infection from the sphenoidal sinus. It is characterized by rapid emaciation, somnolence, amenorrhoea in women, polyuria, atrophy of the sex glands, anaemia, slow pulse and respiration, increasing muscular weakness, atrophy of the skin, and in some cases loss of hair and teeth. Some of the cases have improved on the injection of pituitary extracts, but finally ended in death.

#### DISTURBANCES OF THE SEXUAL FUNCTIONS.

As a rule sexual activity is depressed or lost in all forms of pituitary disease, and this is frequently the first symptom of which the patient complains. Some cases of acromegaly are exceptions: one of my patients begat a child when the enlargement of the pituitary was so great as to cause a serious degree of blindness by pressure on the optic chiasma, and I have recently seen a woman with unmistakable physical symptoms, including blindness of one eye and a temporal hemianopia in the other, whose periods have remained regular and normal during the five years the condition has existed. States of sexual overactivity have also been described in the early stages of acromegaly. In other hypophyseal affections amenorrhoea in women and impotence and lack of desire in men are almost invariably the rule, and often the first symptoms to attract attention. This is particularly true in the case of chromophobe adenomata of the anterior lobe which injure the pars intermedia and posterior lobe, with which the sexual functions are usually correlated; it holds, too, for most suprasellar lesions that compress the pituitary. It must be regarded as a direct consequence of destruction of the gland.

The state of the sexual organs naturally varies with the age at which the symptoms of the disease commence; when the onset occurs before puberty the penis and testes in the male, the uterus, the ovaries, and the external genitalia in the female, remain undeveloped and infantile, and no evidences of puberty appear. If the disease starts after puberty the sexual organs may retain their natural size, but frequently atrophy and regressive changes set in, especially in long-standing cases. Then the penis shrinks,

the testes become small and soft, and often not tender to pressure. The uterus has often been found infantile in shape and size, while the labia and clitoris may atrophy too. This state is associated with loss of all manifestations of sexual function; in the female complete amenorrhoea exists, and none of the accompanying phenomena of menstruation occur, while the male never has erections, omissions, or other sign of sexual activity. A point of some importance in the diagnosis of pituitary impotence is the fact that it does not occasion the patient the worry or distress that impotence from other causes usually does; there is at the same time a complete lack of desire, and in the female absolute frigidity.

An absence or deficient development of the secondary sexual characters usually accompanies this genital atrophy. When the disease sets in before puberty the female breasts are small and contain little glandular tissue, but in adipose types they may be distended by fat. In cases in which the disease develops later in life the mammae may atrophy, though by no means always. In men collections of fat underneath the nipples often produce pseudo-mammae. The general shape and configuration of the patient is often striking, particularly in cases of pre-adolescent onset; in males the body is slight, often broader at the hips than at the shoulders, and frequently shows the tendency to waisted formation which is more characteristic of the female. The limbs are long, the fingers slender and tapering, and the appearance lacks that muscularity which is normally typical of the young adult male, while the type of adiposity, with accumulation of fat on the buttocks and thighs and in the region of the breasts, exaggerates the female-like type of body. In young females the figure is frequently that of a child: the pelvis is narrow, the back straight, the thighs slender, and the pubic region undeveloped. In later life adiposity generally predominates; the abdomen is large and pendulous, the breasts soft and hanging, and irregular pads of fat around the shoulders, loins, and thighs distort the figure.

The amount and the distribution of the hair in the male are important diagnostic points. In the hyperpituitary syndrome there is often excess over the body, which sometimes is irregularly distributed in patches on the back, upper arms, and limbs. In hypopituitary states, on the contrary, hair is scanty and its distribution approximates to the female type. Youthful patients develop no beard or moustache, or at the most there is a soft down on the face. The trunk and limbs are hairless, the axillary hair is usually scanty, and that on the pubis has a horizontal upper limit as it usually has in the female. In patients in whom the condition commences after puberty the hair anomalies are less pronounced. Frequently, however, there is less than the normal amount on the face; many patients, in fact, state that while previously they had to shave every day, once or twice a week is now sufficient. The moustache is scanty and generally retreats from the sides towards the middle line, while the beard is represented mainly by fine hair along the lower margin of the jaw and up the middle line, the skin under the angles of the mouth being more or less devoid of it. The eyebrows are generally thin and there is frequently a deficiency of hair in their lateral parts. In women there are less striking changes; in juvenile cases the pubic hair may never grow, and it is often sparse in older patients. In all types and in both sexes the hair of the head is usually normal in amount, but in hypopituitary cases it is often dry, fine, and thin.

#### METABOLIC DISTURBANCES.

Glycosuria, as has been for long known, is often found in acromegaly, but it is a variable symptom, sometimes present, sometimes absent, regardless of diet or mode of life of the patient. Or it may be produced by a moderate intake of sugar. This glycosuria can be controlled by insulin as easily as that of pancreatic origin. On the other hand, as Cushing and his fellow workers first recognized, in patients with hypopituitary symptoms there is usually a marked increase of carbohydrate tolerance, larger amounts than 150 grams of glucose by the mouth being necessary to produce glycosuria. This test

has been extensively employed as a diagnostic sign, and it is undoubtedly of use, though it has not the absolute value originally attributed to it. There are obvious fallacies in it, since the glucose may not be absorbed from the intestinal tract, or the renal threshold for sugar may be high. The investigation of the blood sugar curve after the administration of glucose either by the mouth or intravenously is a more accurate and more valuable method. In normal subjects the highest point of the curve is reached thirty or forty minutes after the glucose has been given, but Gray, Sachs, and others have found that when the pituitary is injured by experiment, or its functions interfered with by disease, the curve rises more slowly and remains up longer than normal.

In a series of blood sugar investigations made recently on fifty-six patients at the National Hospital this condition was found. In both acromegaly and hypopituitary states the form of the curve was the same, the highest point being reached late, sometimes an hour or more after the administration of the glucose, and it fell to its initial level very slowly. The percentage of blood sugar usually differs with the type of the disease; in acromegalics the resting or fasting sugar tends to be high, while when obesity and other signs of hypofunction are present the fasting blood sugar is small in amount.

Several recent observers have obtained glycosuria by experimental lesions of the hypothalamus only, and clinical cases have been recorded in which it occurred in disease limited to this region. Sachs, for instance, assumes that though it may have a modifying effect on carbohydrate metabolism, the pituitary alone is not responsible for the glycosuria. It has been shown, however, that the intravenous injection of posterior lobe extract can produce glycosuria in healthy persons and lower the tolerance for carbohydrates in states of hypopituitarism, and Burn has found that the simultaneous injection of posterior lobe extract with insulin counteracts the effects of the latter.

Numerous observations go to show that the basal metabolic rate is also lowered in hypopituitary states and raised in hyperpituitarism, but this is apparently not a constant rule. It has been attributed to secondary changes in other glands, especially in the thyroid, and to pressure on the tuber cinereum.

Polyuria and the clinical manifestations of diabetes insipidus have also been attributed to disease of the posterior lobe of the hypophysis. An excessive amount of urine is not, however, a common symptom in the more usual forms of pituitary disease, but diabetes insipidus is often associated with more acute lesions of this region, as basal syphilis and fractures of the base of the skull. Recent observations, both experimental and clinical, have thrown doubt on this explanation of polyuria, and many of them point strongly to its being directly due to injury of the hypothalamus; the temporary relief of the symptoms of diabetes insipidus by injections of extracts of the posterior lobe suggests that the pituitary may play a part in its pathology.

**Blood Pressure.**—My own observations show that in most cases of tumour of the hypophysis both the systolic and diastolic pressures are lower than normal. This is particularly so in the chromophobe adenomata associated with dystrophia adiposo-genitalis; here the systolic pressure often does not rise above 100 mm. of mercury.

Somnolence is not an infrequent symptom in pituitary disease, especially in adipose patients with evidences of hypopituitarism. In these we occasionally observe a tendency, similar to that found after epidemic encephalitis, to sleep excessively by night, and to drop off into sleep at any hour of the day. This is a true and perhaps a wholly natural sleep from which the patient can be easily awakened, and must be distinguished from the stupor with slowing and obfuscation of the mental processes that occurs with cerebral tumours and other lesions that raise intracranial pressure. It is most probably not a direct pituitary symptom, as a series of extremely interesting observations have within recent years demonstrated the existence of a centre in the neighbourhood of the third ventricle which controls or regulates sleep. This region is, of course, frequently compressed or otherwise damaged by hypophyseal tumours.

### PRESSURE SYMPTOMS.

In a large proportion of all cases with clinical symptoms of pituitary disease the primary lesion is a tumour which either arises in the sella turcica or compresses the hypophysis within it. The tumours often attain a considerable size; cysts and other growths from Rathke's pouch are often as large as a walnut, while tumours of the pituitary itself frequently grow out from the sella and surround the base of the brain. Such tumours naturally compress or injure other structures and thus produce other symptoms.

**Headache** is variable. Many patients with even large pituitary tumours complain of little or no pain in the head, but in others it is one of the earliest and most prominent features. When the tumour lies entirely within the sella the headache is most probably due to pressure on its dural lining. It is most commonly referred to the temples, and described as a dull aching or a more severe bursting pain, which is often continuous for hours or days. When the growth originates outside the sella or extends from it the headache is a result of the general increase of intracranial pressure. Then it is usually more severe, but less constant, and is commonly referred to the forehead or behind the eyes; intense bouts occur in the early morning on waking, and are sometimes accompanied by attacks of cerebral vomiting, which is rare in intrasellar tumours.

### Visual Symptoms.

As the optic nerves and chiasma lie in close relation to the sella it is not surprising that visual disturbances are among the most common symptoms of pituitary tumours. These vary from case to case, owing partly to the position of the tumour and the direction of its growth, partly to the variable anatomical relations of the chiasma to the sella turcica. Most commonly its anterior border lies on the sellar diaphragm, and consequently the upward pressure of a pituitary tumour involves first the optic fibres from each nasal half of the retina as they decussate in the chiasma. In other cases the optic nerves are longer and the chiasma more posteriorly situated, so that one or other of the optic nerves is first compressed. More rarely the chiasma is placed anterior to the sella, and then the pressure first affects one of the optic tracts.

Pressure on the chiasma alone produces the characteristic picture of a bitemporal hemianopia. A pure bitemporal hemianopia is, however, rare, for the decussating fibres seldom suffer alone, and they are all affected only when the tumour has reached a considerable size. The loss of vision may develop in several different ways. The earliest defect in the field is usually found in the periphery of one upper temporal quadrant; from here the blindness gradually extends towards the fixation point, and then invades the lower temporal quadrant. The other eye may be affected simultaneously or suffer later. In another type, which is probably as common, a scotoma, at first partial but gradually becoming more complete and larger, is found on the temporal side of the fixation point. This scotoma extends temporalwards, chiefly into the upper quadrant, until it reaches the normal, or more commonly the contracting, periphery. Frequently it spreads over the fixation point or for a short distance above or below it into the nasal fields. In other cases there is a general and gradually increasing contraction of the peripheral temporal field, or there may be merely a progressive diminution of vision throughout the whole temporal field.

When the chiasma is situated more posteriorly in relation to the sella, the tumour first compresses one or other of the optic nerves. The first clinical evidence of this is usually a diminution of central vision, which progresses, often rapidly, to blindness of the eye of this side. As the tumour increases in size it usually involves the chiasma next, producing a temporal hemianopia of the opposite eye; or the second optic nerve may be compressed, with the result that its central vision also suffers. In a patient with an anteriorly placed chiasma, a homonymous hemianopia to the opposite side may be the first visual symptom, but this is uncommon.

Tumours growing from the infundibulum or from the meninges produce similar disturbances of vision; when they lie above the chiasma the loss often commences in

the lower temporal quadrants, owing to the fact that the fibres from the upper halves of the retinae decussate in the upper part of the crossing and are consequently liable to suffer first by pressure.

Associated with the loss of vision we generally find a progressing pallor of the optic discs, giving the ophthalmoscopic appearance of a primary optic atrophy. The discs, however, frequently retain their normal colour for a considerable time after defects in the fields of vision have set in, especially when these develop rapidly. Papilloedema, or swelling of the discs, is rarely seen in simple pituitary tumours, but it occurs frequently with extrasellar growths.

**Ocular Palsies.**—Diplopia, strabismus, and ptosis are not uncommon symptoms. One or more of the muscles supplied by the third nerve may be weak, or all, including the iris and ciliary body, are affected. The external rectus is commonly palsied, but in my own experience the fourth nerve generally escapes. It has been stated that these ocular palsies are found only when there is an intracranial extension of the pituitary tumour, or when the growth lies outside the sella turcica. They are certainly then more common, but I believe they occur even with intrasellar growths, which may bulge lateralwards and compress the ocular nerves, especially when the tumour has extended backwards and eroded the posterior clinoid process.

#### *Trigeminal Pain.*

Occasionally patients complain of pain and numbness on one side of the face, most commonly in the distribution of the ophthalmic or maxillary division of the trigeminal nerve, and examination reveals a defect of sensation in the area to which the pain is referred. These symptoms must be due to compression of the fifth nerve or one of its branches by the tumour; they probably never occur when the growth lies entirely within the sella, and consequently indicate an intracranial extension or a primary extrasellar lesion.

#### *Anosmia.*

Disturbances of smell are rare with pituitary tumours, but extrasellar neoplasms may produce them by compressing the olfactory tracts or the area olfactoria in front of the chiasma.

#### *Cerebral Symptoms.*

In view of the serious amount of compression which the brain may suffer in the case of a large pituitary tumour, and even more so in the case of neoplasms growing from the infundibulum and its neighbourhood, it is surprising that cerebral symptoms are so rare. Occasionally, however, a mild degree of hemiplegia, often indicated only by an extensor plantar reflex, is seen. It is due to compression of one of the cerebral peduncles, and consequently occurs most commonly with extrasellar tumours extending into the interpeduncular space. These may also damage the mesial aspect of the temporal lobe and produce uncinate attacks.

#### *THE PITUITARY AND THE HYPOTHALAMUS.*

I have already referred to the fact that considerable doubt has arisen within recent years on the direct relation of some of the functional disturbances we have discussed with disease of the pituitary.

Karplus and Kreidl originally showed that there exist in the hypothalamus centres which can, under experimental conditions at least, affect the activity of the sympathetic system, and later observers brought further evidence that this region of the brain is concerned in the regulation of temperature and metabolism, in the secretion of urine, in the control of sleep and in the functions of the sex glands. Erdheim first suggested that disturbance of the hypothalamus is the cause of many of the symptoms attributed to the pituitary, and Aschner and others have provided further experimental and clinical evidence in favour of this thesis. Several physiologists now maintain that, contrary to the view generally held, the pituitary is not essential to life, and that its complete removal may not be followed by the characteristic symptoms. It seems to be definitely established that polyuria and temporary glycosuria may be produced by lesions of the tuber cinereum, and some experimenters claim that even adiposity and regressive

changes in the sex glands may result from injury of the base of the brain though the pituitary be intact.

Numerous clinical cases published within the last few years tend to substantiate these experimental conclusions. Diabetes insipidus and glycosuria have been found associated with lesions limited to the tuber cinereum; obesity has been observed in disease of these parts, and even a few more or less typical cases of dystrophia adiposo-genitalis have been recorded in association with encephalitis of the base of the 'tween-brain. It may be that the "pituitary" symptoms resulting from experimental injury or disease of the base of the brain are really the result of blockage of pituitary secretions that normally reach the cerebro-spinal fluid through the infundibulum; further investigations are necessary to settle this point. On the other hand, as Abel suggests, the symptoms that follow hypothalamic lesions may be due to injury of the pars tuberalis of the pituitary which surrounds the infundibulum and extends on to the base of the brain.

Certain clinical syndromes must, however, be correlated with hypophyseal disease. There is now the clearest evidence that acromegaly is associated with an overgrowth of the eosinophil cells of the anterior lobe, and that its constitutional manifestations may precede any evidence of pressure on the brain. It also seems to me certain that disturbances of the functions and anatomical regression of the sex glands are direct pituitary symptoms.

The major clinical manifestations of pituitary disease are not common, but it is probable that certain minor disturbances of health which often escape notice or diagnosis are a result of disturbances of pituitary function. Unnatural obesity, stunted growth, and sexual weakness, for instance, may be of this origin, though accompanied by no other evidences of hypophyseal disease. Some disturbances at the climacteric may be due to imbalance of the activities of the pituitary and the sex glands, and in men certain changes not infrequently seen about middle life may have the same cause. It has been, for instance, suggested that the obesity, sexual impotence, and pathological somnolence of Napoleon at about the period of Waterloo were symptoms of a pituitary affection.

#### *TREATMENT.*

In some cases of pituitary disease the main aim of treatment is to alleviate the symptoms of glandular deficiency, in others it is to relieve the pressure which a pituitary tumour exerts on the optic tracts or other structures, or the headache that it causes.

When the most prominent symptoms are those which we regard as hypopituitary in nature, the most rational procedure would be to administer the active substance of the gland in suitable doses. It is definitely known that the intravenous injection of posterior lobe has an influence on metabolism, and that the intraperitoneal injection of anterior lobe stimulates growth in animals. Similar results, however, have not yet been obtained regularly in patients with symptoms of pituitary deficiency. Cushing, for instance, found that in undergrown children even the intraperitoneal injection of an extract every second day for months had no effect, though others have obtained partial success. It appears, then, that even intravenous or intraperitoneal injections give no constant results.

The efficacy of oral administration is even more doubtful. The notable success in the treatment of myxoedema by extracts of thyroid by the mouth has aroused the hope that other glandular defects may be relieved by similar means, and has created an actively advertised market for various glandular products. There is, however, no evidence I know of that pituitary preparations given by the mouth are absorbed, or that their active principles survive digestion and absorption. I have used them extensively, but I have never satisfied myself that any of them had the least effect in relieving the symptoms of pituitary deficiency. I am aware that others have been more fortunate, though their published results do not inspire very confident hopes. More may be attained by this method of treatment when we can be sure of obtaining a reliably active and accurately standardized preparation.

Other glandular extracts, and especially thyroid, have been employed. There is no doubt that, in some cases of

the adipose type, thyroid in moderate or large doses diminishes weight, reduces somnolence and lethargy, and leads to a subjective improvement at least. It is probable that these effects are due to the direct action of the thyroid, but it is possible that it also acts by influencing hypophyseal cells that persist. The administration of thyroid to patients with large adenomata certainly diminishes the pressure symptoms in many cases; I have repeatedly observed an improvement in vision and diminution of headache under its use. Pituitary extracts are often given with it. Suprarenal, ovarian, and testicular preparations have also been tried, but there is no convincing evidence that they have any effect when administered by the mouth.

When the most urgent symptoms are, as is frequently the case, due to compression by a pituitary tumour of neighbouring structures, as the optic nerves or chiasma, there are only two efficient modes of treatment—surgery and radiology. Operation has now become a relatively safe procedure, though in my opinion it is as yet justifiable only when headache and other pressure symptoms are severe, or when vision is threatened. Unfortunately many cases are referred to the surgeon only when the tumour has attained a large size, or even burst out of the sella into the intracranial cavity; then only a temporary relief of pressure can be expected. The operation may be undertaken by the trans-sphenoidal or by the fronto-temporal route; personally, I have had more experience of the operation that approaches the tumour by elevating the frontal lobe of the brain, and I cannot but believe that it is the most effective, though its mortality may be slightly higher.

X-ray treatment has been extensively employed within recent years, especially by Bédère and other French physicians, and some striking results have been reported. It is claimed that this method is free from danger, and this is probably true so far as life is concerned; but I have seen an increase of blindness and other pressure symptoms, and other cases have been reported, after a few x-ray applications. This method certainly deserves further trial, especially in feeble patients with low blood pressure who do not stand surgical intervention easily.

## II.—NORMAN M. DOTT, F.R.C.S.ED.,

Surgeon, Royal Edinburgh Hospital for Sick Children; Assistant Surgeon, Church of Scotland Deaconess Hospital; Lecturer, Edinburgh University.

(With Special Plate.)

THE treatment of pituitary disorders, as of other diseases, demands of the individual who assumes responsibility therefor as complete a knowledge of the organ concerned as is possible. It is only on such a basis that treatment can be rationally planned and its results correctly assessed. As a surgeon concerned in the treatment of certain diseases of the pituitary gland, I propose to lay before you an outline of their principal features and the factors bearing on their treatment. In doing so I shall be obliged to review the known physiology of the gland, since it is only on a basis of normal function that pathological states become comprehensible. I shall then describe the pathology in relation to the endocrine function of the gland. Lastly, the lesions will be considered in their anatomical and surgical bearings.

In the first place, I wish to acknowledge my indebtedness to the clinic of Dr. Harvey Cushing at Boston, on the staff of which I had the privilege of acting two years ago, and whose rich mine of records I was permitted to explore. Dr. Cushing has been so kind as to send for your inspection most of the microscopic specimens which I have set out.

## I.—PHYSIOLOGICAL CONCEPTIONS OF DISORDERED PITUITARY FUNCTION: HISTORICAL.

As in the case of the thyroid gland so for the pituitary we recognize a state of excessive activity (hyperpituitarism) and a state of insufficient activity (hypopituitarism) on either side of the zone of normal function. It should be of interest to review the salient points in the history of these conceptions.

## Hyperpituitarism—Gigantism and Acromegaly.

Pierre Marie gave the first clear description of acromegaly as a disease entity in 1886. In the following year Minkowski pointed out the association of the disorder with a tumour of the pituitary gland. It is noteworthy that for some years the disease was considered to be an expression of pituitary insufficiency—a very natural conclusion from the presence of a tumour which obviously destroyed the gland. The failure of Horsley and others to induce acromegaly changes in animals by operative destruction of the hypophysis cast doubts on this theory, and led Tamburini, in 1894, to put forward the conception that acromegaly was an expression of hyperpituitarism. The relationship between acromegaly and gigantism was also recognized at this time. In 1900 Benda showed that the tumour concerned was an adenoma of pituitary origin, not a sarcoma or carcinoma, as it had previously been designated: Fraenkel, Stadelman, and Benda, in the following year, called attention to the hyperplasia of eosinophil cells in the tumour, and they regarded this finding as evidence of hyperpituitarism. A decade later the nature of the syndrome of pituitary insufficiency was clearly recognized from animal experiments, and, by contrast, additional strength was given to the view that acromegaly and gigantism were expressions of increased pituitary function. A recent analysis of 162 cases of hypophyseal adenoma from Cushing's clinic, by Percival Bailey and myself, revealed an absolutely constant relationship between the eosinophilic adenoma and acromegaly. The final proof was furnished by Uhlenhuth, Evans, and others, who induced actual gigantism in amphibia and rats by administration of pituitary anterior lobe substance. Evans has actually caused pituitary insufficiency in young rats by operation, and subsequently dispelled its symptoms by injections of a preparation of the anterior lobe.

## Hypopituitarism.

We have no convenient synonym for the term hypopituitarism, as none of the familiar phases or types of the disease, such as hypophyseal infantilism, dystrophia adiposo-genitalis (Frölich), etc., are sufficiently representative of the disease to give it their name. Babinski in 1900, and Frölich in the following year, each described a single case of pituitary tumour associated with genital hypoplasia and adiposity. Neither observer, however, appears to have grasped the conception of pituitary insufficiency in relation to these cases. In 1906 Bartels gave a clear description of the syndrome, which he christened "dystrophia adiposo-genitalis"; he believed that a pituitary lesion had no causal relationship to the symptoms. Cushing, in 1909, reproduced this syndrome experimentally in dogs by partial hypophysectomy, and on this basis first clearly formulated the conception of hypopituitarism. A year later Aschner reported dwarfism as a consequence of similar experiments on young puppies, and thus demonstrated the relationship of infantilism to hypopituitarism. The lowered metabolic rate of pituitary insufficiency was shown both experimentally and clinically by Cushing and Boothby. The clinical and pathological evidence of a recent review of 162 cases of hypophyseal adenoma (above referred to) shows that all tumours or other destructive agents acting on the hypophysis, with the single exception of the eosinophilic growth, cause hypopituitarism.

It is interesting to observe that of the two syndromes hyperpituitarism was by far the earlier to be understood, and that its elucidation came primarily from the hospital ward and pathological laboratory. Hypopituitarism was not recognized until fifteen years later, and was then brought to light in the experimental laboratory. In both instances it is instructive to consider how the clinical, pathological, and experimental avenues have alternated and interwoven in advancing our knowledge, and encourages us to anticipate further progress along similar lines.

## II.—THE PHYSIOLOGICAL FUNCTIONS OF THE PITUITARY GLAND.

In discussing the physiology of the hypophysis I shall dwell briefly on those functions of which we possess substantial proof, but shall touch also on some related phenomena of less certain origin. At the same time, in

DEC. 4, 1926]

# NORMAN M. DOTT: PITUITARY DISORDERS.

[THE BRITISH  
MEDICAL JOURNAL

FIG. 1.—Pituitary adenoma. Typical x-ray appearance of sella turcica. Note the characteristic even "ballooning." Film by Dr. Hope Fowler. J. W., female, aged 40; Deaconess Hospital, 1925; transphenoidal operation with marked improvement to vision.

FIG. 3.—Hydrocephalus due to pericerebellar adhesions. Ventriculography. Air outlines enormously distended anterior horns. The third ventricle is seen to dip into the flattened sella turcica. The dorsum sellae is eroded. Note marked atrophy at vault and rapping of coronal suture. J. S., male, aged 15; Deaconess Hospital, 1926; cerebellar decompression; adhesions freed. (Film taken with head in inverted position.)

FIG. 2.—Suprasellar cyst. Typical calcification in solid base of tumour. Slight erosion of posterior clinoid processes. (Film by Dr. Hope Fowler.) Female, aged 11. Private series, 1923. No operation possible.

FIG. 4.—Large right parietal glioma. Typical pressure atrophy with obliteration of dorsum sellae, thinning of floor and anterior clinoid processes and orbital plates; stippling of inner table over vault. (Film by Dr. Hope Fowler.) Male, aged 42. Private series, 1925. Wide decompression over growth.

## E. GRAHAM LITTLE ACUTE NODULAR LEPROSY.

FIG. 1.—Face, before treatment.

FIG. 2.—Face, after treatment.

FIG. 3.—Back of trunk, before treatment.

CASE I.—Spiral fracture of tibia. (a) After nine days' ordinary treatment. (b) After operation.

CASE III.—Fracture of humerus in a woman aged 30. (a) After three weeks' treatment. (b) After operation. Note the slight projection of the proximal end of the distal fragment.

CASE II.—Spiral fracture of femur in a girl aged 8. (a) After one week's treatment. (b) After operation.

CASE IV.—Spiral fracture of humerus in a woman aged 30. (a) After operation. (b) Complete recovery of humerus. Note the slight projection of the proximal end of the distal fragment.

consideration of the dogmatic statements often made as to anterior and posterior lobe symptoms, it may be well that we should inquire into the actual state of knowledge concerning the individual lobes.

#### *The Posterior Lobe (Partes Nervosa, Intermedia, and Tuberalis).*

Knowledge of the functions of this structure remain very scanty and uncertain at present. The activity of extracts of the posterior lobe in raising the blood pressure and in causing a transient diuresis was shown by Schafer with Oliver and Magnus at the outset of this century. Their observations have been followed by a host of others, demonstrating the potency of the extract in causing contraction of plain muscle in the uterus, eye, bladder, stomach, and intestines; showing its prolonged anti-diuretic effect, its action on the pigment cells of amphibia, its influence on capillary tone, and its quantitative effect in inducing the onset of parturition. It should be emphasized, however, that although these observations show that the extract has powerful pharmacological activities, and may be suggestive as to the purpose of the organ in the body, they actually prove nothing as to the normal physiological functions of the posterior lobe. The single proven function which I know of for this part of the gland is the regulation of pigment cells in the skins of certain amphibia. These animals remain pale after removal of the posterior lobe; they become temporarily black again on injection of the extract, and remain permanently black after successful grafting of pars intermedia tissue. In considering the possible purposes of the posterior lobe in the mammalian economy it is important to recollect that the total removal of this organ in the dog is unattended by any observable consequences to the animal. Many independent workers have confirmed this. At the present time it may be interesting to mention a particular instance in one of my own experiments. I observed a collie bitch from which the entire posterior lobe had been excised for several years. During this period she remained a perfectly natural and healthy animal. She had three normal pregnancies, terminating in due course in normal parturitions. The completeness of the excision was verified at subsequent autopsy by microscopic examination. I feel, therefore, that suggestions as to the possible functions of the posterior lobe should be made with great reserve at present. It appears to me quite unwarranted by known facts to attribute any definite symptom of pituitary disease to derangement of this structure.

#### *The Anterior Lobe (Pars Distalis).*

We have much more definite information concerning the normal activities of this gland. As already indicated, some of its functions were early suspected from clinical and pathological evidence in cases of acromegaly and gigantism. The probability that it was concerned with growth, with the development and maintenance of the functions of the sex glands, and with the maintenance of the normal metabolic rate, was strengthened by disturbances of these functions following its experimental removal. Experiments on the administration of the anterior lobe or its extracts remained somewhat inconclusive until, in 1917, P. E. Smith caused tadpoles, which had remained dwarfed after hypophysectomy, to grow again by anterior lobe feeding. Evans completed the evidence by similar experiments on young rats, employing intraperitoneal injection as the method of administration. The relation of the eosinophilic cells of the anterior lobe to these phenomena is rendered almost certain by their constant hyperplasia in clinical hyperpituitarism and their marked diminution or absence in the presence of hypopituitarism. It is of great importance to note that experimental hyperpituitarism in rats is always associated with cessation of sexual functions, just as in hypopituitarism. The sex glands would appear to be governed by a delicate balance of anterior lobe activity. True experimental gigantism has been induced by anterior lobe administration to certain amphibia and rats. In these particular animals natural growth does not cease abruptly, but continues slowly throughout their lifetime. In the human giant similar conditions exist. Before growth is

complete he develops hyperpituitarism, his genital glands fail to mature, his epiphyses therefore fail to close at the normal age, and at the same time are stimulated to grow by hyperpituitarism; and, in fact, growth often continues until 30 or more years of age in such a case. We must again pay tribute to an early observer, for this is no new conception of gigantism. Tandler, in 1910, expressed the view that the eunuch is potentially capable of increasing in stature on account of the absence of puberty and its associated epiphyseal closure; that he actually does attain an abnormal stature is the result of hyperplasia of the pituitary, which constantly follows castration. He applied this reason . . . . . Nothing resembling the changes of . . . . . reproduced by experimental administration of anterior lobe. This raises the question as to whether the secretion of the eosinophilic tumour cells may not be merely excessive, but also qualitatively abnormal.

#### *"Pituitary" Symptoms of Uncertain Origin.*

*Adiposity* is an inconstant, though often a striking, accompaniment of hypopituitarism. It varies with age, being much more frequent and conspicuous in the young, and decreasing both in frequency and degree as the age of onset of the disease advances. A comparison with the adiposity of castration and the recollection of the genital hypoplasia of pituitary insufficiency suggest that the symptom may be due to an indirect effect through the intermediation of the genital glands. On the other hand, some recent experimental evidence points to the possible existence of a fat-metabolism centre in the hypothalamic region of the brain. It is quite possible that implication of this region by the tumour may be responsible for adiposity. The cause of adiposity in pituitary disease remains uncertain at present.

*Diabetes insipidus* is a very inconstant accompaniment of tumours of the pituitary region. It may also follow encephalitis affecting this neighbourhood. It has been attributed on the one hand to lesions of the posterior lobe, and on the other to lesions of the adjacent hypothalamic region of the brain. A study of tumours of the neighbourhood indicates that diabetes insipidus occurs only when the growth is large enough to indent the base of the brain, but it does not always accompany this event. Experimental evidence strongly favours the cerebral theory. It is, however, very difficult to regard as mere coincidence the fact that injections of posterior lobe extract will arrest the polyuria of diabetes insipidus. We must leave this an open question at present.

*Diabetes mellitus* of acromegaly is also a very inconstant symptom. It may occur early or late in the disease. It appears to differ from typical diabetes mellitus in one character, being extremely irregular and often transient in its appearance. It may be of severe degree for a few days or weeks, and then completely disappear spontaneously, to return in weeks, months, or years, or not at all. When present it reacts to insulin treatment as does true diabetes. Two cases under Dr. Cushing's observation have died in typical diabetic coma. In one of these cases some of the islets of Langerhans show sclerosis. It is difficult, however, to associate an intermittent symptom with a sclerotic process. Again we must leave this question open.

*"Increased Sugar Tolerance."*—It has been observed that the obese subjects of hypopituitarism can ingest larger quantities of sugar without exhibiting glycosuria than normal subjects. The phenomenon is not specific for hypopituitarism, but may be observed in any form of obesity with lowered metabolism. I have observed that if the sugar is injected intravenously a glycosuria and blood sugar curve is obtained in hypopituitarism which does not differ from the normal. The inference is that the abnormality in the ingestion test lies in the rate of alimentary absorption and is probably an expression of the general metabolic depression. I would emphasize the gross fallacies to which sugar ingestion tests are liable. All such investigations should be made by the intravenous route, and further, a continuous injection regulated by grams per hour is essential.

### III.—PITUITARY DISORDERS IN RELATION TO DISTURBED ENDOCRINE FUNCTION.

Having reviewed the known functions of the pituitary gland, we may now correlate the various pathological lesions of the organ with the train of symptoms due to disordered glandular activity which they engender.

The evolution of our knowledge of disease of any organ is usually characterized by a period in which isolated symptoms and numerous clinical and pathological types are described, and they tend to accumulate into a complex and chaotic mass. Finally, scientific investigation succeeds in correlating and arranging this mass into a much simpler and clearly comprehensible form. I hope to show that such simplicity of conception is applicable to pituitary disorders. Its outline was clearly delineated in Cushing's *Disorders of the Pituitary Gland* in 1911.

We have to deal with two main types, between which a borderland will be recognized. The eosinophilic adenoma accompanied by hyperpituitarism constitutes one main type; the chromophobe adenoma and all other lesions which destroy or compress the hypophysis, accompanied by hypopituitarism, constitutes the other. Between these a smaller group, characterized by a mixed adenoma and by mixed hyperpituitary and hypopituitary symptoms, is distinguished.

#### *The Eosinophilic Adenoma and Hyperpituitarism.*

The *eosinophilic adenoma* possesses the characters of a true neoplasm in its loss of architectural arrangement and in definite modifications of its component cells, both as to form and relative proportions. The eosinophilic cell preponderates and shows considerable variation in size and shape. Rarely it is exclusively present. More frequently there is a proportion of chromophobe cells, and they resemble those of the normal gland, though showing some variation in size and form. The supporting stroma may be extremely scanty or quite dense, according to the proliferative activity of the particular tumour. Thus the growth may be almost self-limiting or may cause a rapidly enlarging tumour. The presence of the eosinophilic adenoma in acromegaly and its absence in hypopituitarism are absolutely constant.

*Pathological hyperpituitarism* is first manifested by general overgrowth if the patient is still within the growing period. Growth persists beyond the normal limits both of age and stature, and gigantism results. It is accompanied by acromegalic changes, and these changes usually become pronounced at a later period. If, as is more frequent, the state first appears in adult life, acromegaly alone ensues. Its earliest symptom is usually a fibrous hyperplasia in the subcutaneous tissues of the fingers, lips, nose, and ears, followed by similar changes in the tongue, internal organs, and nerve sheaths. Overgrowth of the bones of the face and hyperostosis of the vertebral column, ribs, and limb bones follow. The metabolic rate rises progressively, though never so markedly as in hyperthyroidism. Loss of sexual function is constant, but may be comparatively late in onset. Hypertrichosis and glycosuria are inconstant and somewhat infrequent signs. In the later stages toxæmia, presumably the consequence of continued excess of the pathological pituitary secretion, dominates the picture, inducing asthenia and often emaciation.

#### *The Purely Destructive Lesions and Hypopituitarism.*

In this category we have to deal with a variety of pathological conditions, which are here grouped together because they are all associated with hypopituitarism by reason of their injurious effect on the pituitary body. Among them are numbered the chromophobe adenoma, the suprasellar cyst of Rathke's pouch, and various other suprasellar growths, such as meningioma, cholesteatoma, glioma, etc. Hydrocephalus may compress the hypophysis by forcing the brain down into the sella turcica; and, indeed, chronically increased intracranial pressure from any cause—for example, a large tumour at a distance from the sella—may induce hypopituitarism in the same way. Of these causes the chromophobe adenoma and suprasellar cyst are by far the most frequent. The suprasellar cyst is a simple squamous epithelial neoplasm derived from the primitive tubular outgrowth from the buccal ectoderm from which the epithelial portion of the pituitary body takes origin.

Its base, lying just over the sella, is composed of a solid mass which projects in wart-like processes into the upper cystic portion, which occupies the interpeduncular space. The solid portion is usually calcified. The growth is of the nature of an adamantinoma.

The *chromophobe adenoma* is selected for special description in order to contrast it with the eosinophilic adenoma. The chromophobe tumour consists of a mass of cells which are devoid of specifically staining granules. They differ considerably from the fully developed chromophobe cells of the normal gland, being of a more or less embryonic type. They are usually elongated or columnar in form, but may be irregularly rounded. They are arranged either in acinar formations or quite irregularly. The cell type is uniform. Eosinophilic cells are absent (or practically so). The stroma varies, but tends to be scanty. The tumour is usually one of comparatively active growth.

*Hypopituitarism*, if its onset occurs during childhood or adolescence, causes retardation or cessation of growth resulting in some degree of dwarfism. The sex glands fail to mature, the epiphyses remain unclosed, and secondary sex characters do not appear. Thus the subject is physically infantile in every respect. Mental development is usually normal. When the condition arises during adult life the earliest symptom is invariably a depression of sexual function—an occurrence which is very clearly indicated in women by the onset of amenorrhœa. The only other constant sign is some degree of hypotrichosis of the limbs and trunk and of the face in men, together with a peculiar fineness of the skin. The cutis is thin, soft, and pliable, and in patients over 40 years of age the skin exhibits a characteristic fine wrinkling. The secretion of sweat is usually diminished. Probably a depression of the basal metabolic rate is also constant, but the finer degrees of variation are difficult to detect with certainty by clinical calorimetry. The metabolic rate is not nearly so markedly as in striking in the young; it rarely appears after the age of 40.

#### *The Mixed Adenoma and Dyspituitarism.*

The *mixed adenoma* possesses the general characters of the chromophobe tumour, but its cells exhibit some degree of eosinophilic granulation. The granules may be present as a thin ring at the periphery of each cell, or a few scattered but typical eosinophil cells may be present in a tumour chiefly composed of pure chromophobe elements.

*Dyspituitarism* or the mixed clinical syndrome is by no means uncommon. The patient who is somewhat overgrown, who has large bones and air sinuses, but who at the same time exhibits hypotrichosis, fine soft skin, and genital atrophy, is quite familiar. Less common perhaps is the combination of definite infantilism with acromegalic thickening of the fingers, lips, and nose. It is notable that the degree of eosinophilia in the mixed adenoma is constantly reflected by the degree of pathological hyperpituitarism in the associated mixed syndrome.

When we look for an explanation of these definite glandular syndromes, we find it in the histological type of the tumour. All the adenomata are exactly similar in their gross anatomical appearance and in their pressure effects, and all destroy the normal pituitary gland. The eosinophilic cells are the distinguishing feature of the particular tumour associated with clinical signs of pathological hyperpituitarism, and it is reasonable to assume that these cells are responsible. It is interesting to reflect that the eosinophilic tumour most closely resembles the normal anterior lobe and represents its most highly specialized cell form; it might be expected to secrete something resembling the normal anterior lobe hormone. No specific secretion would be expected from the chromophobe adenoma, which represents the least specialized cell type and usually attains only an embryonic phase of this cell. It has been indicated that good reasons exist for suspecting that the secretion of the eosinophilic neoplasm may be qualitatively abnormal as well as excessive, hence I have used the term "pathological hyperpituitarism." The mixed adenoma and dyspituitary syndrome strongly supports this view, for were physiological hypopituitarism and hyperpituitarism present they should tend to equalize each

other, causing little or no disturbance of function. In actuality definite acromegalic changes may occur in the presence of undoubted hypopituitarism, indicating that acromegaly is to be considered as a pathological state, as contrasted with a simple exaggeration of a physiological state.

#### *Latent Hypopituitarism.*

I use this term to designate a group of cases—"cases with pronounced neighbourhood but inconspicuous glandular symptoms," as Cushing described them in 1911. These cases, recognizable only from the effects of tumour pressure on the optic fibres, etc., occur in persons over 40 years of age. The lesion is usually a chromophobe adenoma. Their explanation is very simple. It has been pointed out that certain cutaneous changes and depression of sexual function are the only constant signs of hypopituitarism, and that adiposity does not supervene in later life. In the female the onset of amenorrhoea after 40 has no obviously pathological significance; and in the elderly male loss of sexual desire may not attract attention. The inconspicuous hypotrichosis and finely wrinkled skin are not likely to arouse suspicion in a patient over 40 years of age. A chromophobe adenoma large enough to involve the optic fibres has certainly compressed the hypophysis at an earlier period, and hypopituitarism is undoubtedly present in these cases. The recognizable symptoms of this condition are masked, however, by the natural phenomena of advancing years. Hence the expression "latent hypopituitarism" appears appropriate.

#### *Adenocarcinoma of the Pituitary Gland.*

This is an extremely rare affection. The few cases of which I have been able to find record were in patients over 45 years of age. The growth evinces a definite tendency to invade the bones of the cranial base and to spread between them and the dura. The fibrous dura seems to offer a barrier against intracranial invasion. The signs are those of progressive involvement of the cranial nerves. In one case all the cranial nerves with the exception of the auditory and facial on one side were completely interrupted. The growth may produce typical metastases in the liver and elsewhere.

#### IV.—PITUITARY DISORDERS FROM THE ANATOMICAL AND SURGICAL STANDPOINT.

When pituitary disorders are regarded from the technical surgical point of view, histological and endocrine grouping falls into comparative abeyance. The pathology must be rearranged on an anatomical basis. We must distinguish three main groups: (1) lesions of intrasellar origin, (2) lesions of suprasellar origin, (3) increased general intracranial pressure. Such grouping is essential to differential diagnosis and efficient treatment.

#### *Tumours of Intrasellar Origin.*

By this term I would imply those growths which arise within the sella turcica, though by the time they cause symptoms they have usually trespassed its limits. They are the pituitary adenomata, and are by far the most frequent lesions encountered. Let us consider the enlargement of such a tumour, the structures it successively encounters and the effects it thus produces.

It first compresses the soft and yielding parent gland, inducing hypopituitarism (acromegalic signs will appear in spite of this if the tumour happens to be eosinophilic). Distending the dural capsule of the sella it causes typical headaches. Distending the bony wall of the sella it causes a characteristic ballooning of this structure which is evident on the x-ray film. Squeezing itself outward between the two layers of the dura it displaces the cavernous sinuses and surrounds the internal carotid arteries; in doing so it may cause an abducens paralysis. It may thus reach Meckel's cave and so induce paraesthesiae and sensory loss in the upper divisions of the trigeminal nerve. Rupturing the dural roof of the sella it encounters the optic fibres, usually at the chiasm, and thus gives rise to characteristic bitemporal defects in the visual fields and primary optic atrophy. It next impinges on the base of the brain, inducing polyuria (probably), somnolence, and

sometimes acute hyperthermia, which may cause death. Its further upward extension gradually obliterates and obstructs the third ventricle, causing hydrocephalus with signs of general increase of intracranial pressure. If it bulges outwards it may crush the oculomotor nerve against the sharp dural edge of the sella, or impinge on the inner surface of the temporal pole—whence olfactory hallucinations. Continued downward pressure irritates the sphenoidal sinus and induces congestion and catarrh of its mucous lining, evidenced by slight recurrent epistaxis and post-nasal dripping. I would especially emphasize here how even a tumour of moderate size will surround the carotid arteries and insinuate itself between the layers of the basal dura—facts which render its complete operative removal out of the question.

#### *Tumours of Suprasellar Origin.*

In this category I include those growths which arise from or near to the roof of the sella turcica, which enlarge primarily in the space afforded by the cisterna chiasmatis, though by the time they cause symptoms they have usually encroached on the sella and its contents by pressing down its roof from above. In their upward enlargement most of these growths pass behind the optic chiasm towards the third ventricle and interpeduncular space. They differ from the intrasellar tumours, not only in their origin, but in their relation to the subarachnoid space, and in the sequence in which they encounter the various structures which they press upon and the direction of this pressure. Thus polyuria and somnolence may appear as early symptoms. There may be a significant difference in the position and mode of progress of the visual field defects, since the pressure often comes from above and behind the chiasm. The appearance of the sella turcica as revealed by radiography differs entirely from that of the intrasellar growth. There may be erosion of the clinoid processes and flattening of the sellar outline by pressure from above, but never the even distension characteristic of the pressure from within of the adenoma.

#### *General Pressure causing Hypopituitarism.*

To those who are familiar with the striking appearance of the flattened sella, as disclosed by x-ray examination or at necropsy, in any case of long-standing intracranial hypertension, it cannot be surprising that definite signs of hypopituitarism may sometimes result from this cause. I have seen the pituitary signs so well marked in cases of hydrocephalus secondary to mid-brain tumour and to chronic adhesive meningitis that, at first sight, one would incline to regard them as instances of primary pituitary disease. An interesting recent example was that of a young woman who had a very large temporo-occipital meningioma. The skiagram showed well marked erosion of the dorsum sellae, and complete amenorrhoea had supervened. Normal menstruation returned immediately after removal of the growth, and has remained regular since. In such cases careful inquiry will usually reveal that the hypopituitary symptoms were of comparatively late onset, while the presence of definite signs of involvement of a region distant from the sella will deflect the diagnostic search in the correct direction.

#### V.—DIFFERENTIAL DIAGNOSIS.

A definite differential diagnosis between pituitary lesions of intrasellar, suprasellar, and distant origin is almost always possible. Its importance cannot be overestimated, since the most efficient operative treatment of the three groups differs very materially, and since an incorrect surgical approach may not only be inadequate but highly dangerous. The diagnosis of a tumour in the neighbourhood of the pituitary is usually very obvious, and does not require further discussion here. Some factors in the differentiation of these growths may, however, be of interest.

The age of the patient may be of assistance. Adenomata are extremely rare before the fifteenth year, and quite uncommon before the twentieth. The suprasellar cyst is frequently encountered in young children, and the vast majority manifest themselves before the age of 30. The

chronology of the symptoms and the nature of the visual field defects will assist in many cases. The x-ray appearance of the sella turcica is of paramount importance. The even ballooning caused by the intrasellar adenoma (Fig. 1) is quite characteristic. The isolated clinoid erosions of the suprasellar cyst and its calcification which is present in 85 per cent. of these cases form a well marked contrast (Fig. 2). When the sella is affected by general intracranial hypertension there is erosion of the prominent clinoid processes and dorsum sella, but in addition other portions of the base and vault of the skull show evidence of pressure atrophy. The floor of the sella and orbital plates are thinned, and the inner table of the skull, especially over the vault, shows stippling and erosion (Fig. 4). It should be noted in passing that clinical signs of such chronic hypertension are not always very obvious; headache and vomiting are frequently absent.

To be sure, difficulties may arise in the differential diagnosis. For example, it may not be easy to decide between a suprasellar cyst or tumour without calcification in it and a cerebellar lesion with accompanying hydrocephalus. It is notorious that the neurological picture in some of these basal tumours may be very similar. Each of them is capable of causing hydrocephalus, and in the absence of calcification of a suprasellar cyst the x-ray appearances may be quite indistinguishable. In a recent case of this nature, in a child aged 15, in which the diagnosis of chronic adhesive meningitis about the cerebellum with secondary hydrocephalus seemed probable, there were such obvious signs of hypopituitarism and sellar erosion that an uncalcified suprasellar cyst with hydrocephalus could not be excluded by all ordinary diagnostic methods. Since the surgical approach in the former condition would be by the suboccipital route, and in the latter by a transfrontal procedure, a definite decision had to be reached. The matter was settled by ventriculography. The film (Fig. 3) has been taken with the head in the inverted position. The air, attempting to rise, has outlined the third ventricle against the base of the skull. The ventricle is seen to dip right into the flattened sella turcica, leaving but little room for the hypophysis—far less for a suprasellar growth! The initial and correct diagnosis was thus verified.

As experience of these cases increases, and diagnostic measures are improved and new ones evolved, the doubtful case is becoming rare.

#### VI.—TREATMENT.

It remains for us to consider how the patient afflicted with a tumour in the vicinity of the pituitary body may be benefited. Three means are at our disposal: (1) surgical operation, (2) radiotherapy, (3) glandular therapy.

##### *Operative Treatment.*

*Indications.*—The indications for surgical intervention are fairly clear. Amelioration of symptoms of glandular disturbance following operation has been recorded in a very small proportion of cases. For example, return of menstruation, and even fruitful pregnancy, has followed partial removal and decompression of the growth, presumably from relief of pressure on some remaining glandular tissue. In the case referred to in Fig. 5 sexual desire and potency have been recovered. Very exceptionally acromegalic changes have definitely receded after partial removal of the responsible tumour. Improvement of glandular symptoms has been rare, however, and as they alone are seldom a very serious inconvenience to the individual, they do not constitute an indication for operation at present. The persistence of severe headache and progressive failure of vision, on the other hand, are symptoms which demand relief more urgently. When the position is explained to the patient he is usually willing to submit to operation on these grounds. It is of the utmost importance that surgical treatment should be carried out reasonably early, as the risk is less at this time and as marked benefit to vision is assured. The frequent examination of the visual fields and acuity usually furnishes us with dependable evidence regarding the behaviour of the tumour. Operation should be strongly urged when the

visual fields or acuity are progressively decreasing, and also in cases of any severity, if actual improvement in these respects is not occurring spontaneously.

*The Adenoma.*—The impossibility of total removal in practically all cases coming to operation must be clearly recognized in the first place. All those with large experience in this field of surgery are in agreement on this point. The impropriety of exposing the patient to what is necessarily a very hazardous attempt on the basis of so forlorn a hope is obvious. This being the case, we have to reckon with the likelihood of further enlargement of the growth after partial removal at operation. If this subsequent enlargement is allowed to occur in an upward direction the temporary benefit gained by a partial removal will be lost. The only means of preventing upward extension is to induce the enlargement to take place in a downward direction. This implies the creation of a sufficient breach in the bone and dura of the sellar floor, which can only be effected by an approach from below. In other words, a sellar decompression by the transphenoidal route is indicated. Since the pressure within the cranium is higher than that in the sphenoidal sinus the growth is partially extruded into the latter, and any further enlargement tends to take place in a harmless downward direction.

The fear of sepsis has deterred some from this operation, but extensive experience has shown this objection to be negligible in comparison with the advantages. It is true that a potentially septic field is traversed in the operation from below, but the relationship of the adenoma to the leptomeninges renders the potential sepsis of little practical significance. The tumour originates in the sella, below the cisterna chiasmatis of the subarachnoid space, and, in enlarging, it lifts the cistern away from the sella turcica. The tumour itself constitutes a thick barrier between the leptomeninges and the danger zone of the sphenoidal sinus. It is instructive to note that those who have recorded by far the largest series of pituitary operations are now in agreement that the transphenoidal procedure is the operation of choice for the adenoma. Hirsch (1926) and Frazier (1925) record excellent results, and apparently base their preference on the much lower mortality rate which the operation has given in their hands as compared with the intracranial approach. Cushing's preference is influenced less by the comparative mortality rate than by the degree of benefit which the operations confer. His statistics (1925) show a mortality of 7.38 per cent. in a total of 203 transphenoidal operations, and this figure has been reduced to 2 per cent. in his last fifty cases. The fatalities following thirty-five transfrontal operations have been 5.7 per cent. In his hands, therefore, there is little to choose between the two, and the risk in either case is indeed very slight considering the nature of the malady. At his clinic the much more durable benefit derived from the transphenoidal operation, as contrasted with the usually temporary relief gained by the transfrontal method in adenoma cases, has been most striking and is the important factor. Thus, from every point of view—the comparative simplicity of the technique, the low mortality rate, and the more permanent relief to the patient—the transphenoidal procedure is the operation of choice for the pituitary adenoma.

As performed by Cushing, the operation involves no external incision. The frenum of the retracted upper lip is incised and the anterior edge of the nasal septum exposed. A submucous resection of the septum is carried out. Between the layers of muco-periosteum thus separated a speculum is passed to the antero-inferior wall of the sphenoidal sinus. When the latter has been removed the bulging floor of the sella lies exposed. The floor is in turn removed, producing an aperture which varies from 10 to 20 mm. in diameter. The dural capsule of the tumour is now incised. As a rule, the soft, tense neoplasm partially extrudes itself at once through the incision. So much of the growth as is thus spontaneously forced out is removed with the spoon. Occasionally a tumour of unusually firm consistence will not come down at the time of operation. In these circumstances a fragment may be removed for examination, but no attempt should be made to clear out the contents of the sella. In the course of a few days or weeks the tumour will become moulded to the shape of the

aperture under the influence of normal intracranial pressure, and it will then slowly descend. Convalescence is usually smooth, and the patient is able to leave hospital in ten or fourteen days. Patients frequently notice the improvement of vision so soon as they recover consciousness. The results in the restoration of vision are often dramatic (Fig. 5). The post-operative prognosis is difficult to give at present. Formerly from five to eight years of freedom from symptoms could be expected. To-day x-ray treatment is found to have a very powerful influence on these adenomata, and it is to be anticipated that the duration of benefit after operation will be greatly prolonged by this means. In exceptional cases the transfrontal operation as described below may be carried out as an adjunct to the transphenoidal procedure for an adenoma in which there is evidence of a large intracranial protrusion which will not descend satisfactorily into the decompression. In the event of recurrence of visual symptoms the fibrous tissue which eventually forms around the extruded growth may be freed by a second transphenoidal operation and further extrusion thus permitted, or a further portion of the growth may be removed by a transfrontal approach.

**The Suprasellar Tumour.**—The primary factors which dictate the mode of surgical attack on these tumours are their relation to the leptomeninges and the possibility of their total removal. As already indicated, these neoplasms grow primarily in the cisterna chiasmatis. As they enlarge, therefore, they dis tend this portion of the subarachnoid space and remain surrounded by the leptomeninges, so that the outer layer of the pia-arachnoid membrane lies between the growth and the base of the skull. An approach from below would necessarily involve the opening of the leptomeninges and subarachnoid space under possibly septic conditions before the tumour could be reached. This consideration alone renders a transphenoidal operation out of the question for a tumour originating above the sella turcica. The second

factor which demands an approach from above is that a proportion of suprasellar growths are amenable to complete removal. While the adenoma is a soft diffuse neoplasm, and insinuates itself between the layers of the basal dura, the suprasellar tumour is usually of a more circumscribed character, and lies entirely within the dura. Frequently it cannot be completely extirpated on account of its size or its relation to important structures. Nevertheless, this should be the ideal of its operative treatment, and has been successfully accomplished in a proportion of cases. Ample access to the region of the optic chiasm and interpeduncular space is essential, and can only be provided by an approach from above. Various operations have been advocated for exposure of this region—transfrontal, fronto-temporal, and temporal. That which has given the most satisfactory results and is now employed by the majority of those experienced in this field is the transfrontal procedure. An osteoplastic flap is elevated from the right frontal bone (in the absence of special indications for a left approach); the flap hinges in the temporal region. The dura is separated from the roof of the orbit and incised along the lesser wing of the sphenoid and outer edge of the cribriform area. Elevation of the frontal lobe, protected by its dura, now gives excellent access to the hypophyseal region. If possible, the tumour or cyst is removed completely. If this cannot be accomplished, considerable, though comparatively temporary, relief can be expected from partial removal.

The role of subtemporal decompression in cases of pituitary tumour is a very minor one. It is obvious from the position of the lesion and the fixation of the optic nerves to the base of the skull that no benefit to vision could be anticipated by decompression from above—rather the reverse. Since general hypertension in association with pituitary disease is usually due to a secondary progressive hydrocephalus, a decompressive operation fails to relieve it. It could only be reasonably used as a palliative for hypertension in a patient already hopelessly blind, and when the hypertension was due to the size of the growth without complicating hydrocephalus. These are very exceptional circumstances.

I do not wish to belabour the subject of the choice of operation unnecessarily, but I feel that it is a most important one. The pioneers of pituitary surgery naturally inclined to favour one or other method in their early endeavours, but, as already indicated, the recent views of those with greatest experience are unanimous in favouring the transphenoidal operation for the adenomata and

the transfrontal operation for the suprasellar tumours. It is also their experience that a correct differential diagnosis can now be made in the vast majority of cases. When doubt does exist as to the nature of the lesion a transfrontal exploration is the only safe course, as the risk of exposing an intrameningeal tumour through the sphenoidal sinus would be extreme. The surgeon is responsible for the method which he adopts, and he must be familiar with the diagnostic features of the various lesions which may give rise to hypophyseal symptoms, in order that he may assess their significance and direct his procedure accordingly.

#### Radiotherapy.

Deep radiation has a powerful destructive influence on the neoplastic cells of the pituitary adenomata, but not on other tumours of this region so far as is known. That caution must be exercised in employing it as a primary measure in the treatment was shown by a

trial of preliminary radiation in a series of cases at Cushing's clinic. Two of these cases indicated the danger of radiotherapy in the absence of a sellar decompression opening. In them such a degree of reactive swelling occurred in the tumours that the pressure symptoms became acutely aggravated, and immediate sellar decompression had to be carried out. In cases with very early visual symptoms a trial of radiotherapy without previous operation may be justifiable. Certainly, when the optic fibres are already seriously compressed, it should not be employed until a transphenoidal operation has been done. As a post-operative adjunct it is most valuable; and undoubtedly promotes the improvement which has followed the operation alone. There is every reason to anticipate that it will go far in retarding or preventing further enlargement of these growths. Several treatments are usually given on successive days before the patient leaves hospital, and this should be repeated at intervals of one or two months, according to the indications of the particular case. The visual fields are, of course, kept under frequent observation meanwhile.

Radium has been employed by some by means of an endonasal applicator. The results, so far as I know, have not been superior to those of x-ray treatment, and a number of complications, such as necrosis of adjacent bone, have been recorded.

FIG. 5.—Visual fields one day previous to and three months after transphenoidal operation for pituitary adenoma. (Charts by Dr. H. M. Traquair.) R. S., male, aged 47; Deaconess Hospital, 1925; chromophobe adenoma, hypopituitarism. Subsequent radiotherapy by Dr. Hope Fowler.

*Medicinal Treatment.*

*Diabetes Insipidus.*—The constant thirst and great frequency of urination associated with this malady are most distressing symptoms. They can be greatly relieved or even abolished by administration of pituitary posterior lobe extract. This is most conveniently accomplished by the intranasal spray; 0.5 to 5 c.cm. of the standard preparation used in obstetrical practice is employed daily or twice daily, according to the demands of the particular case. The effect is obviously of great interest in relation to the function of the posterior lobe, though it cannot yet be explained in terms of normal physiology. It is interesting to note that incidental pyrexia and simple lumbar puncture may occasionally cause temporary cessation of polyuria and thirst.

*Pituitary anterior lobe and "whole gland" administration* by various means has been extensively employed in clinical cases of hypopituitarism (and in many other conditions). A study of the literature on the subject is by no means convincing as to the efficacy of this treatment. Nevertheless, a sure foundation is being laid at present in the experimental laboratory, where very definite amelioration of the symptoms of artificial hypopituitarism has been obtained in mammals by intraperitoneal injections of large doses of anterior lobe substance. The active principle has not yet been isolated, and suitable means for its administration to the human subject have not yet been contrived. One can hardly doubt that before long such means will be at our disposal.

## DISCUSSION.

Mr. M. L. HINE (London) treated the investigation of cases suspected of pituitary disorder from the ophthalmological point of view, and mentioned the importance of using various sizes of test objects, or in some cases coloured test objects. It was frequently found that while little change in field was present in one quadrant with a 10 mm. white test object, yet with a 5 mm. or 3 mm. test object, or with a red test object, there was definite alteration. If a smaller test object, such as the normal 5 mm. white one, was used at the start, and a defect found, it was necessary in making a prognosis to test the field with larger objects (10 mm. or 20 mm.), or, more accurately, with those numbered by the degree of angle subtended on the retina. It was evident that if, using the larger test objects, a field was obtained, there was not complete atrophy of the conducting fibres, and the prognosis was correspondingly hopeful after the tumour pressure had been removed. In addition to Mr. Dott's criteria for operation—namely, pressure symptoms indicated by headaches and increasing depreciation of visual fields—Mr. Hine urged the importance of taking very careful fields with graduated test objects. Walker's papers on this subject from Cushing's clinic should certainly be studied by all neurologists and ophthalmologists. Traquair's paper in the *British Journal of Ophthalmology* in 1917 would also repay careful study.

Dr. W. J. ADIE (London) said that the part of Dr. Gordon Holmes's comprehensive paper which he would like to amplify was that dealing with the relation of the pituitary body to the nervous structures that lay above it in the floor of the 'tween-brain (thalamencephalon). There was no need to emphasize the close anatomical connexions between these parts; the posterior lobe, the nervous part of the gland, was nothing more than a process from the floor of the 'tween-brain with which it was connected by stout bundles of nerve fibres in the stalk. The anterior lobe; the glandular portion, was continued upwards in the stalk by a process which certainly reached the region of the chiasma, sometimes extended to the tuber cinereum, and even further into the substance of the 'tween-brain. Secretions from the gland also found their way to the 'tween-brain through the stalk. The vegetative centres in the 'tween-brain therefore were bathed by glandular secretions, while the gland in its turn was subject to a nervous control from these centres, directly through the stalk in the case of the posterior lobe and indirectly through the sympathetic in the case of the anterior lobe. This close anatomical relation suggested an equally close physiological relation. Dr. Adie submitted that these two parts—the

pituitary body and vegetative centres in the floor of the 'tween-brain—formed an intimately connected physiological mechanism which might be called the "pituitary-'tween-brain system." He further suggested that the same symptoms and syndromes might arise from disease strictly confined either to the glandular or to the nervous part of this system. As Dr. Holmes had said, Karplus and Kreidl first showed that various disturbances in the vegetative nervous system could be produced by experimental lesions in different parts of the 'tween-brain; others had obtained results which proved the existence in this part of centres the integrity of which was essential for normal temperature regulation, fat, water, and sugar metabolism, and activity of the sex gland. Destruction of the temperature-regulating centre, for example, rendered animals poikilothermic, so that it was impossible to cause a rise of temperature in them by infection or by any of the many methods by which fever might be produced experimentally in normal animals. Further, it had been shown that minute lesions confined to the 'tween-brain, and certainly sparing the pituitary body and its stalk, could cause glycosuria or polyuria and be followed by obesity and atrophy of the genitals; clinical evidence—for example, the behaviour of the temperature in encephalitis lethargica—supported these results; the sudden rises of temperature in this disease without corresponding increase in other symptoms were most easily explained by assuming that inflammation had affected the temperature-regulating centre (Economo). The speaker was convinced that irregular pyrexia might be the only symptom for many months in patients who ultimately developed the post-encephalitic Parkinsonian syndrome. In two of his cases the diagnosis of tuberculosis had been made in the pre-monitory stage. Again, moderate or extreme obesity, slight or severe polyuria, glycosuria and dystrophia adiposo-genitalis, were well known sequels of encephalitis lethargica—a purely nervous disease with a predilection for the grey matter in the mid- and 'tween-brains—and in other conditions affecting the infundibular region. These and similar facts had caused some to maintain that the above-mentioned symptoms were always of 'tween-brain origin and that the pituitary body never played any part in producing them. It had been said, for example, that diabetes insipidus was always of 'tween-brain origin. Dr. Adie was sure that this was not true. A case of his had been published by Dr. Piney, in which the diagnosis of secondary deposit of carcinoma confined to the posterior lobe of the pituitary body was confirmed *post mortem* in a woman with severe diabetes insipidus whose breast had been removed for cancer. One observer collected thirty-two cases in which lesions strictly confined to the posterior lobe caused polyuria. Those who denied that polyuria might result from uncomplicated pituitary disease asked why this syndrome was not more frequent in pituitary tumours, and why, with an increasing lesion, polyuria often ceased. The reason seemed to be that polyuria occurred when the posterior lobe alone was diseased; if both lobes were damaged there was no polyuria, and when disease spread to the anterior lobe it ceased (Hann). The pituitary body certainly played a part in the normal regulation of temperature, for it had been shown that extirpation of the gland or division of its stalk produced exactly the same results as injury to the centre in the 'tween-brain, and that injections of pituitary extract counteracted the effects of this extirpation. He asked if the temperature was lower than normal in these patients; if there was anything noteworthy about the daily variation in temperature; had any of them passed through an acute infection? Unequivocal experimental and clinical evidence existed in favour of the view that disease confined to the pituitary body could also cause obesity, atrophy of the genitals, and other endocrine disturbances. He was forced, therefore, to conclude that the symptoms under consideration might be produced by a purely nervous or a purely glandular lesion, and that the pituitary body and vegetative centres in the 'tween-brain worked together as equivalent parts of an endocrine nervous system. At present investigators seemed to be divided into two camps—those who maintained that the pituitary alone was responsible for certain symptoms, and those who attributed them all to disease in the 'tween-brain, denying that the pituitary

played any part in their production. If the view Dr. Adie had put forward was correct, both assumptions were wrong; as Professor Schiff had said, it was not a matter of "either-or" but of "not only—but also."

Dr. H. GARDINER-HILL (London) referred particularly to the question of obesity and growth disturbances in children and their relation to pituitary disease. A considerable proportion of cases was suggestive of dyspituitarism, including a number of apparently the true Fröhlich type, in which there was no demonstrable evidence of a pituitary or suprasellar tumour. In over a hundred children with clinical features suggestive of pituitary disturbance, and in whom the carbohydrate metabolism was altered in the way which Dr. Gordon Holmes had mentioned as characteristic of pituitary disease, they found evidence suggestive of pituitary or suprasellar tumour in only about 10 per cent., and those were cases of the true Fröhlich type with lack of growth and genital hypoplasia. The tumour, though unverified, appeared to be suprasellar, judging by the changes in the optic discs and visual fields and the absence of any enlargement of the sella. There was also a high proportion in which the syndrome of obesity, overgrowth, and early development occurred without evidence of pituitary tumour. In these children the obesity was often extreme at the age of 14 or 15; they might weigh as much as 15 or 20 st. The condition very frequently developed after one of the infectious illnesses of childhood, and the obesity was first noticed during convalescence. It appeared especially liable to develop if the infectious illness occurred at the time of the second dentition or at puberty. In some cases there was undoubtedly a diätetic factor, but in the large majority there was no history of alteration in diet or of overfeeding or lack of exercise. The onset of obesity was accompanied by marked acceleration of growth, which continued until puberty, when it ceased. Puberty occurred early, at 11 or 12, and growth then ceased. If an x-ray examination of the bones was made, it was found that the bone development was advanced, and in many cases the epiphyses were already fused. The skeleton was large, and the condition appeared to be the opposite of that found in Fröhlich's syndrome, where there was delay in the appearance of the centres of ossification and late fusion of the epiphyses. The secondary sexual characteristics developed early, and in girls menstruation commenced before the usual age. It might at first be excessive; in a considerable number, however, it was normal, though after a few years many patients suffered from periods of amenorrhoea. Estimations of the sugar tolerance showed that the carbohydrate metabolism was abnormal; in some the tolerance was decreased, in others it was markedly increased. There was seldom any alteration in the sella turcica, though in a fairly large proportion it was frequently found to be rather below the average size. This syndrome was relatively frequent in the speaker's series of cases, while the type described originally by Fröhlich was comparatively rare. The question arose whether they were justified in attributing this overgrowth obesity syndrome to pituitary disturbance in the absence of neighbourhood signs. If there was any evidence of pituitary tumour the clinical features would fit in very well with those of the mixed type of adenoma described by Mr. Dott in his paper in the *British Journal of Surgery*, in which symptoms of the hyper- and hypo-pituitary syndrome were combined; but in the speaker's cases there was seldom any indication of tumour. One striking point of similarity, however, in the two syndromes was that in both cases the hyper- and hypo-pituitary symptoms developed concurrently. There is other recent work of interest in this connexion. Evans and Long, in their work on the intraperitoneal injection of anterior lobe extract in rats, not only found marked acceleration of growth with increase in size of the skeleton, but they also remarked on the large deposit of fat which was found in the injected animals.

Mr. GEOFFREY JEFFERSON (Manchester) dealt with the question of operative treatment, and more particularly the relative merits of the transfrontal and trans-sphenoidal methods of approach. As a mode of access for super-pituitary lesions, for the Rathke pouch tumour, and supra- or para-pituitary endotheliomas, the transfrontal operation

was obviously the method of choice, and there was no disagreement on this point. It was in the treatment of the true intrasellar tumour, the pituitary adenoma, that opinions had diverged almost to the point of bitterness. At the best, what could be done with the pituitary adenoma? Could they expect to remove it completely, or did they hope at most to relieve local pressure? There could be but one answer in general to this question. The pituitary tumour was not a malignant growth. It was a serious, and indeed a fatal, tumour only because of its position, which endowed it with the power of destroying sight, of paralysing the ocular muscles, of involving the trigeminal nerve by extension, of projecting upwards into the third ventricle and so interfering with cerebro-spinal fluid drainage, and of causing such local pressure damage as might give rise to uncinuate attacks and the like. They could relieve these pressure effects by either of two methods, which were in their essence quite different. By the transfrontal operation the tumour might be directly attacked and as much as possible removed by curette and by suction. The beneficial results were here obtained by actual reduction of tumour mass. The trans-sphenoidal operation, on the other hand, was a local decompression, the floor of the sella being removed widely and crucial incisions being made in the inferior part of the capsule of the adenoma to allow of its extruding itself downwards, extracranially, where it could do no harm. The improvement looked for here was obtained by the reduction in intracranial tumour mass by its extracranial protrusion. The adenomata were on the whole of soft consistency, often cystic in part at least, and when the capsule was incised the adenomatous tissue escaped and could be removed. But no attempt was made to scrape the tumour out from the sella, and ill results were likely to follow if this was done, because a dam must be left behind to block the way from the nose through to the intradural space. The transfrontal operation would appeal most readily to the surgeon, because it was an osteoplastic operation of much the same type as that which he was often doing there, and elsewhere on the skull, for other conditions. The trans-sphenoidal route was an unfamiliar one to him, involving as it did a submucous resection of the nasal septum and the chipping away of the anterior wall of the sphenoidal air sinus; but it was not a very difficult matter with suitable instrumentation and help in the early days from specialist colleagues. The speaker had dwelt on the essentials of the two operations, because the objects of the trans-sphenoidal operation were not well understood generally in this country. Its disadvantages leapt to the mind immediately, the chief of these being sepsis. Cushing had repeatedly tried to dispel this boggy, and in his last series of fifty cases had only one death. While none of them were likely to rival these figures yet, they would get nearest to them by limiting the operation to its essential, a sellar decompression. It was obvious that the best results would occur with the soft tumours, and that the hard type, almost like tough thyroid adenomatous tissue, would not give equal results. But even these, as he had reason to know, were capable of slowly extruding themselves, and fortunately this type was distinctly uncommon. The opponents of this route were apt to point to massive adenomata extending high into the skull and ask what the trans-sphenoidal operation could do for such as these. Little was likely to be gained by argument on pathological curiosities, for which probably nothing could be achieved by any operation. The great advantage of the transfrontal route was that it allowed of a correction of the diagnosis, as, for instance, where the sella had been destroyed by a distended third ventricle in hydrocephalus, cases which they had all seen. So that where there was doubt the transfrontal route was unquestionably the one to follow.

Dr. ELIZABETH C. EAVES (Sheffield) said that Dr. Gordon Holmes and Dr. Adie had referred to the theory advanced by several workers on the subject that lesions in hypothalamic nerve centres might bring about conditions of infantilism and the train of symptoms occurring in hypopituitarism. She was interested in Dr. Adie's statement that either a glandular or a nervous lesion might be the cause of dyspituitarism, as her own observations inclined her to the same opinion. She mentioned two cases of

hypopituitarism in which she examined the brain and the pituitary; in neither case was there a tumour. The first was a girl of 16, very adipose, of stunted growth and with an abnormal condition of the limbs. There was no lesion discovered in the brain, but the pituitary was about half the normal size and considerably fibrosed. The second case was one of infantilism resembling somewhat the Lorain type, and polyuria was present. The whole brain was very abnormal, the condition being the rare one of hypertrophic sclerosis. The pituitary was small, compressed by a dense capsule of connective tissue, and both anterior and posterior lobes were abnormal. In one case of epidemic encephalitis, with Parkinsonism and great wasting and terminating by respiratory failure, there were marked changes in the pars anterior of the pituitary which might account for the cachexia.

Apart from lesions in the hypothalamus and in the pituitary, there was possibly a third way in which hypopituitarism might be brought about—namely, by changes in other ductless glands. It was noteworthy that in children treated for diabetes with insulin for long periods the appearance was rather suggestive of dystrophia adiposogenitalis. She thought it worth while to ascertain if repeated injections of insulin in rabbits caused any alteration in the size and histological appearance of the pituitary. It should be mentioned first that the weight of the pituitary could be altered by several conditions; thyroid feeding was found to cause a slight decrease. After thyroidectomy, three weeks previously, the weight of the pituitary in one rabbit was more than double that in a normal animal. Pregnancy usually caused a hypertrophy of the gland. In five rabbits injected for varying periods of time with moderate doses of insulin the pituitary was above the average weight in every case. The average weight of the pituitary in fourteen control animals was 21.8 mg., that in the insulin-injected animals 30.4 mg. Histologically there were changes both in the pars intermedia and pars anterior. In the pars intermedia there was an enlargement and blurring of the cells, which sometimes merged into a mass of secretion. In the pars anterior the number of eosinophils seemed increased; the cells were larger than normal and confluent. The changes observed indicated increased activity of the pituitary. In a second series of animals insulin was given in about five times the amount in the first series. Cysts were present in the pars intermedia, and the cells of the pars anterior were chiefly chromophobe. These changes probably signified an exhausted condition of the gland. There was another way in which changes could be brought about in the pituitary. In examining the pituitary glands from rabbits in which Dr. G. A. Clark had cut the right vagus at varying intervals of time previously, she was struck by the large size of the glands in many cases, and was led to investigate the histological appearances. Up to the present the appearances found had not been compared with those of strict control animals, but the difference between the pituitary after vagotomy and that in normal rabbits was a marked one. Dr. Clark had suggested (in a paper now in the press) the possibility of inhibitory fibres in the right vagus to the islets of Langerhans. Removal of this inhibitory influence would cause increased insulin production. The changes found in the pituitary glands of the vagotomized animals were found to be very similar to those previously found in the insulin-injected rabbits.

Dr. C. G. IMRIE (Sheffield) described a case of polyuria following encephalitis lethargica which he had recently had the opportunity of investigating; the polyuria was controlled by injections of pituitrin. For diabetes insipidus pituitrin was not necessarily a specific, as J. B. S. Haldane had shown that the substance would control the polyuria following the ingestion of large quantities of water. In cases with a low blood-sugar figure the effect of pituitrin was to cause an increased rise in the percentage of blood sugar, thus rendering the growth more normal. Indeed, 0.5 c.cm. of pituitrin had a greater effect on raising the blood sugar than 50 grams of glucose. It was conceivable that in the pars tubalis there was a sympathetic nervous control of the pituitary gland similar to that controlling the adrenals.

## TREATMENT OF SPIRAL FRACTURES.

A PAPER READ IN THE SECTION OF SURGERY AT THE ANNUAL MEETING, NOTTINGHAM.

BY

A. B. MITCHELL, O.B.E., B.Ch., F.R.C.S.I.,  
Surgeon, Royal Victoria Hospital, Belfast.

(With Special Plate.)

SPIRAL fractures, as revealed by x rays, are much commoner than was formerly supposed. In the absence of complete reduction of the deformity and the maintenance of accurate apposition of the fragments, this fracture gives rise to very prolonged incapacity. Treatment is complicated by two difficulties: (1) the tendency of the sharp ends of the fragments to become deeply and firmly embedded in the muscles of the limb; (2) by the rotation of the distal fragment which, if it can be corrected, is very difficult to keep corrected.

A good stereoscopic x-ray photograph which will enable us to decide whether the spiral is right or left handed is essential. This having been obtained, reduction under full anaesthesia is attempted, rotation corrected, and suitable apparatus to maintain extension and apposition is applied.

At the end of a week a further skiagram is taken. It is surprising how often it will show either (a) that reduction has been incomplete, or (b) that rotation of the fragments has recurred. In this event, given favourable surgical conditions and efficient operative skill, there should be no hesitation in recommending operation.

The following method will be found simple, rapid, and efficient.

1. The fracture is exposed by a suitable incision.
2. The ends of the fragments are freed and brought out into the wound. (The medullary canal will be found plugged with organized blood clot, which is not disturbed, except any projecting portion which may prevent accurate locking of the fragments.)
3. A piece of silver wire is now slipped over each end of the bone.
4. The bones are replaced, and an assistant extends and rotates till the fragments are accurately locked.
5. The wires are placed one at each end of the spiral, where they are secured by twisting slowly and firmly till they have a tight grip.
6. The wires are then cut short and the ends turned down against the bone.
7. The wound is closed in the usual way.

As the wires do not penetrate the bone there is no tendency to rarefying osteitis with subsequent loosening, which is the great defect in methods involving the use of screws or wires traversing the cancellous tissue.

If the spiral is a very long one it is possible to substitute kangaroo tendon or catgut for the silver wire, using three or four strands. It is difficult, however, to tie these substances sufficiently tight to ensure absolute immobility; apposition is consequently not so perfect as with wire. There is, however, an obvious advantage, in the fact that no persistent foreign body is left behind.

Treated in this way the limb need only be fixed in splints for a short time and muscular movements commenced at the end of a week. Patients with fractures below the knee may be allowed to walk at the end of a month, and enjoy full use of the limb in two months. A longer time must, of course, be allowed for the femur. In either case the period of incapacity will be reduced to a minimum owing to the accuracy of apposition, and the small amount of callus required for repair.

[Photographs of cases illustrating the operation and its results were exhibited. See Special Plate.]

## DISCUSSION.

Professor R. E. KELLY (Liverpool) said that torsional strain always produced a spiral fracture, and he demonstrated how the direction of the force influenced the form of the fracture, and how on one side the periosteum was usually preserved. A knowledge of the mechanism of production was essential in order to bring about reposition.

Mr. E. FINCH (Sheffield) said that he had performed the same operation for dislocation of the clavicle as Mr. Mitchell, but he used kangaroo tendon, and also made a new capsule over the joint with fascia lata. A professional footballer upon whom he operated was able to play again in six months.

Sir W. DE COURCY WHEELER (Dublin) said that he had given up operating on all these fractures for a number of years now. He used spinal anaesthesia for reduction and, if necessary, put a pin over the tendo Achillis to obtain a sufficient grip for traction. This was done on the fracture table, and plaster was then applied. He only operated upon cases which proved intractable to this treatment, and then he only replaced the fragments and treated the limb as he had outlined. In children, although reduction might be very imperfect, in two to three years the anatomical results had proved extremely good.

Mr. MITCHELL, in reply, said that he did not recommend routine operation upon fractures, but he thought it caused less disability if operation was performed in some cases.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### RUPTURED SPLEEN: SPLENECTOMY: RECOVERY.

THE following brief account of a somewhat unusual case—namely, ruptured spleen, splenectomy performed after four days, with recovery, despite the supervention of empyema as a post-operative complication—may be of sufficient interest to merit publication.

John R., aged 9, was admitted to the Bury Infirmary on June 9th, 1925, at the request of his own doctor, who suspected the possibility of injuries to his ribs with intrathoracic complications.

**Previous History.**—The patient stated that, four days before admission to hospital, he fell from the window-sill at school, a height of about six feet, but arose unhurt. When he got home he felt dizzy and faint, and was put to bed, his own doctor being sent for, who gave him a bottle of medicine. He felt better the next day, but was still kept in bed. On the evening of the third day he became rather restless, and complained of vague abdominal pain. His removal to hospital was ordered early the following day.

**Examination.**—The patient was extremely restless and pale, pallor of the lips and finger-nails being very marked, and he complained of intense pain in the upper abdomen, which was referred to the left shoulder. Temperature 97° F., pulse 132 and very weak, respirations 32 and very shallow. There was marked tenderness all over the left hypochondriac and the epigastric regions, and movable dullness in the flanks was easily demonstrated. No fractured rib could be found clinically. I informed the parents that the child had a ruptured spleen, and advised immediate operation as an absolute necessity; to this they assented.

**Operation.**—The abdomen was opened by a right paramedian incision above the level of the umbilicus, and was found to be filled with free blood. The spleen, which was delivered through the abdominal wound, was torn at the upper pole (the tear extending through the entire thickness of the organ); it was removed, and the abdomen closed. Immediately on his return to the ward he was transfused with a pint of (citrated) blood and started on continuous rectal salines by the Murphy drip method.

**Progress.**—For two days his condition was very precarious. The salines, with 5 per cent. glucose and half an ounce of brandy to the pint of saline, were continued, and 1/2 c.cm. doses of pituitrin given hypodermically every four hours during the day and night until twelve doses had been given (during the forty-eight hours). On the third day he rallied, and was put on a sparing but nourishing fluid diet. Thenceforth he began to mend very rapidly; the diet was increased, and liberal amounts of minced raw sheep spleen, spread on bread, were given. On the sixth day after operation he developed a troublesome cough, and appeared ill. The pulse rate increased from 80 to 90 to 126 per minute, and the respirations from 28 to 46 per minute. He remained ill for four days, the temperature rising to 100° F. or more each night and falling to normal in the morning. There were profuse night sweats. Examination of the chest revealed loss of breath sounds and marked dullness over the left base. When aspirated, a syringe of pus was drawn off.

**Thoracotomy and Drainage.**—Under local (novocain) infiltration anaesthesia a portion of rib was resected and the empyema drained. The nourishing diet was continued and stimulants were given. On the fifth day after thoracotomy the tubes were entirely dispensed with, and by the sixteenth day the wound was perfectly healed. After this the patient made a very rapid and uneventful recovery, and was discharged on July 30th in an excellent state of convalescence and with both the abdominal and thoracic wounds perfectly healed.

He came to see me recently for examination, and now, fifteen months after the operation, he is a fine healthy lad, with the left lung functioning fairly well. The only sequel I can find is a definite lateral curvature of the spine (scoliosis). The blood picture is perfectly normal, without even the faintest suggestion of a secondary anaemia.

I am extremely indebted to Dr. J. C. Turnbull of the honorary surgical staff, under whose care the case was admitted, for kindly permitting me to publish these details.

I. R. ROSIN, M.B., B.Ch., B.A.O. Univ. Dubl.  
Senior House-Surgeon, Bury Infirmary.

#### TWENTY-TWO YEARS A CARRIER.

A SMALL outbreak of enteric fever—five cases with one death—occurred in Edinburgh in February, 1926. Milk was suspected as its cause, and the infecting supply was tracked down to a dairy in Dumfriesshire. Dr. W. S. I. Robertson investigated conditions in the dairy, and obtained blood, urine, and faeces from those engaged (three persons) in milk distribution. This material was subjected to bacteriological examination (enterica group) with the following result:

Mrs. X.—Serum, 1 in 50, showed complete agglutination against *B. typhosus*; 1 in 150 incomplete. Both faeces and urine were negative.

Mr. X. and D. X. (the other persons examined) gave negative results.

Mrs. X., showing this serum titre, was further examined. She stated that she had been in Pilton Fever Hospital in Edinburgh suffering from typhoid fever twenty-two years ago. This illness she had quite forgotten all about.

Further specimens of faeces in glycerin saline were obtained from her and sown in brilliant green peptone water, and plated to six MacConkey plates. From these plates three colonies were isolated, each of which was true to sugars, and agglutinated with Oxford serum to 1 in 1,000 and to her own serum to 1 in 1,250. This procedure was repeated a few days later with a similar result. She was removed from the dairy.

The interest here is the long period of time—namely, twenty-two years—during which she remained a carrier. The case is published at the request of Dr. John Ritchie, county medical officer of health, Dumfries.

W. LEONARD FORSYTH, M.B.,  
Major I.M.S. (ret.), Bacteriologist to Dumfriesshire.

#### ERYTHEMA NODOSUM IN MEMBERS OF A FAMILY.

THE following cases are, I think, worthy of record, owing to the fact that three different members of the same family, living in the same house, contracted the same uninfected disease.

On June 4th, 1926, I was called to a girl aged 12 years. She had a temperature of 100° F., pulse 110, sore throat, and acute pains down the lower part of her legs. I found a well marked purpuric urticarial rash, thickly distributed over both tibial regions. The patches were exquisitely tender to touch. With absolute rest the symptoms soon subsided.

When visiting her on June 10th I found her grandmother, aged 53, confined to bed with exactly the same symptoms—rash over the tibial region tender to the touch, sore throat, rapid pulse, and high temperature.

On visiting both my patients on June 14th I was astonished to find a man, aged 34, lying in bed with a temperature of 102.5° F., pulse 120, sore throat, and the same purpuric urticarial rash, distributed in patches over the tibial regions, but, in addition, there were very small patches over both elbow regions and also in the spinal region around the vertebra prominens.

The patients did well, with complete rest and salicylates as the main treatment, with the exception of the girl, who developed a systolic regurgitant murmur, which persists at the time of writing.

I confidently diagnosed erythema nodosum in each case, but on searching the literature on the subject I can find no record of this seemingly "infectious" nature of the disease.

D. GORDON ROBINSON, L.M.S.S.A. Lond.,  
Surgeon, Hull and Sculcoates Dispensary.

## British Medical Association.

## CLINICAL AND SCIENTIFIC PROCEEDINGS.

## ULSTER BRANCH.

THE opening meeting of the Ulster Branch for the session was held in the Medical Institute, Belfast, on November 18th. The retiring President, Dr. D. P. GAUSSEN of Dunmurry, thanked the members of the Branch for their cordial and kind support during his year of office, and introduced his successor, Dr. JOHN S. MORROW, who took the chair, and read his address entitled "Some points in medical examinations for life assurance."

Dr. Morrow said that the British Medical Association was fast nearing its centenary; it was founded in 1832, and now numbered 32,000 members. The Ulster Branch had striven to keep before it the objects of the Association—to increase and diffuse medical knowledge, to promote research, to watch over and defend the interests of the profession, and to encourage and foster friendship and mutual esteem among medical men that they might the better discharge their onerous and often trying duties to their patients and to the public. These ends were all the more indispensable now that the profession was exposed to attacks by organizations which promulgated in journals opinions which they, as trained and educated medical men, could not but look upon as dangerous to the community.

*Medical Examination for Life Assurance.*

The examination for life assurance was generally a simple and routine matter to the experienced physician; but many young men, trained in hospital to look for and to diagnose disease, found a difficulty in estimating the expectation of life of an apparently healthy man. To do so with confidence and reliability required a sound professional knowledge, good common sense, as much experience as possible, carefulness, and a certain discerning sympathy with the frailties of life. The medical examiner and referee was only one link in the chain of evidence; the reports of the agents and local managers, of the friends, and the final judgement of the chief medical officer at headquarters, were all evidential. A young medical practitioner should weigh the answers of the overconscientious and garrulous applicant; of the unwilling proposer out of whom he must dig all information; of the important business man who says there is no necessity for him to strip; of the hustling, well nourished, florid type who says he has never been refused; and of the elderly man who is applying for life assurance for the first time. As regards the actual examination, this should always be made without anyone present, and in a good light; male applicants should be stripped to the waist. Much stress was rightly laid upon the careful examination of the apices of the lungs, but the bases must never be omitted. Life assurance companies always laid great stress on heredity. Early senile decay and longevity were both found in families. One death from cancer in a relation might be ignored, but two demanded loading. In tuberculosis both the tendency to consumption, which was hereditary, and the accident of living with an infected patient must be considered; the older the applicant in the first instance and the longer the interval of time since exposure to infection in the second, the less was the danger. The causes of death known as "childbirth," "congestion of lungs," and "bronchitis" must always be closely and searchingly inquired into, as pulmonary tuberculosis was not infrequently cloaked under such a disguise. Body weight must also be fully discussed, and where no evident cause of excess either way could be discovered, the 15 or 20 per cent. departure from average weight-height ratio must decide the acceptance or refusal. Syphilis was another factor, and opinion had become more and more stringent. It must never be forgotten that curing symptoms did not mean the elimination of the disease. Tabes and general paralysis might still be coming in the future. Companies relied chiefly on the history, the thoroughness of treatment, the absence of recurrences, and the presence of healthy children; no one

should be accepted in any case in the first three years after an initial sore, and an increased premium was demanded for the next ten years. No one acquiring syphilis after 40 should be accepted; a Wassermann test was often of great help. Albuminuria had been found present in 16 per cent. of schoolboys, and severe physical exertion would excite it in most adolescents. Its disappearance with a four-day course of calcium and a clear biochemical renal test would render acceptance possible. In glycosuria the habit in some people of eating unduly large quantities of sweets or sugar, and also the low sugar threshold of some kidneys, forming renal glycosuria, must be investigated before rejection, a blood sugar test being required. In both functional albuminuria and in temporary glycosuria no trace of the classical signs of either condition should be present. The acceptance of certain heart conditions had been said to depend on the skill and bias of the examiner; a murmur always indicated something, but it had been proved clearly, and was generally accepted, that many soft systolic murmurs were of no vital significance. An aortic systolic murmur should always be fully investigated with regard to the possibility of stenosis of the aortic orifice. The heart should always be examined both in the supine and erect positions; a mitral stenosis might manifest itself only on exertion or in the recumbent posture. This lesion and aortic incompetence were for practical purposes uninsurable, although occasionally very mild forms, where no symptom and no cardiac enlargement were present, might be taken with safeguards. In cases of cardiac irregularity an electro-cardiograph record and the results of the exercise test should be obtained. Sinus irregularity and that due to respiration and some forms of extra-systoles did not debar acceptance, but the other forms were prohibitive. In low blood pressure careful search for tubercle should be made, and with high pressure kidney and cardio-vascular trouble in an incipient stage might be threatened.

Dr. LESLIE proposed and Professor MACILWAINE seconded a hearty vote of thanks to the President for his clear, practical, and instructive address, which was the fruit of long experience and thoughtful observation.

Dr. DARLING (Lurgan) showed a specimen of a large uterine fibroid, weighing 8 lb., that he had just removed from a pregnant woman, lately married, aged 27, without inducing abortion or performing Caesarean section. Some years ago he had had a successful case of the same nature, and although the woman aborted some weeks afterwards, yet, later, she had a successful pregnancy and safe delivery of a living son.

## CITY DIVISION.

*Treatment of Gastric Diseases.*

A MEETING of the City Division was held at the Metropolitan Hospital on November 2nd, when thirty-six members were present, and Professor HUGH MACLEAN of St. Thomas's Hospital gave an address on modern views on the treatment of gastric diseases.

Professor Maclean first discussed the normal conditions of the stomach. During a meal the hydrochloric acid and pepsin increased, and with them the sodium chloride. With digestion in progress there was a regurgitation of alkaline pancreatic fluid from the small intestine, which neutralized the acid in the stomach. Lack of gastric juice did not set up gastric symptoms, the real digestive juice being pancreatic. The stomach was not required if the food was thoroughly masticated; it acted as a feeder and prepared food for entrance to the intestine. Ulceration was associated with the action of hydrochloric acid on the stomach, since it was confined to the "hydrochloric acid area." All evidence went to show that there was no risk of cancer following ulcer of the stomach or duodenum. Only 3 per cent. of cases of cancer of the stomach gave a history of symptoms which might suggest previous ulceration. While x rays were often not very helpful in the diagnosis of ulcer of the stomach, they were nevertheless sometimes very useful in cases of suspected cancer, where they often gave definite results. With test meals 88 per cent. of hospital cancer patients showed no hydrochloric acid. In the past lactic acid had

often been confused with hydrochloric acid. Duodenal ulcer was more common than gastric ulcer, and ulceration did not occur in areas where free hydrochloric acid was not present. If a case presented symptoms suggesting cancer with achlorhydria and lactic acid present then it was almost certainly cancer. When pain disappeared on a liquid diet there was generally no ulcer. Most patients with dyspepsia had hyperacidity, the hydrochloric acid and pepsin continuing to be secreted after digestion of the meal, when they were no longer required. Gastric diseases might be divided into the functional, including hyperacidity and hypoacidity, and the organic—namely, ulcers of the stomach and duodenum, gastritis, and cancer. In gastric ulcer the operation of gastro-enterostomy should be the last resort; its usefulness depended on the fact that it rendered the stomach contents permanently alkaline. Without an operation good results might follow an attempt to change the reaction of the stomach contents by medical means. In ulcer there was a tendency to hyperacidity; the ulcer was irritated by the gastric juice and the symptoms were increased. If the contents were kept alkaline the symptoms disappeared. With intensive alkaline treatment the results were often extremely good. Hydrochloric acid was deleterious to active ulcers while alkaline pancreatic juice was not; the stomach must therefore be kept alkaline by a powder of equal parts of the carbonates of magnesium and bismuth with sodium bicarbonate. A teaspoonful in water every two hours kept the stomach alkaline in the daytime. At bedtime a tablespoonful was given, and also in the middle of the night if the patient awoke with pain. For ten days the daily diet was three pints of milk and Benger's food; then toast and custard followed by fish, the ordinary diet being reached in four to five weeks. Smoking was very injurious, and meat was kept to a minimum. The administration of the powder was gradually reduced to thrice daily, then to twice daily and at night. This gave a chance for the irritated surface of the ulcer to heal, and the symptoms were relieved. If the symptoms did not disappear the diagnosis was generally wrong; if medical treatment failed a surgical operation was required. At his hospital clinic hundreds of these cases were treated, with only a few operations each year. As regards diet, mastication was absolutely the most important consideration, and meat was kept to a minimum. A large meal was harmful, and salads, vegetables, and condiments were bad. On the whole a surgical operation was not always a cure for gastric ulcer; many failures were met with. In haematemesis from gastric ulcer rest combined with intensive alkaline treatment gave the best results, and also prevented its recurrence.

After a considerable number of questions had been put and answered, the evening terminated with a vote of thanks to the lecturer, which was heartily acclaimed.

#### SOUTH WALES AND MONMOUTHSHIRE BRANCH.

##### *Sympathetic Ophthalmia.*

THE autumn clinical meeting of the South Wales and Monmouthshire Branch was held at the Royal Gwent Hospital, Newport, on November 18th, when the President, Dr. R. PRICHARD (Cardiff), was in the chair.

Dr. W. J. ROCHE read a paper on sympathetic ophthalmia, the cause of which was in most cases a perforating wound in the ciliary region or danger zone. When the ciliary body or iris prolapsed and was incarcerated in the wound the dangers were increased, but when suppurative occurred in the injured area sympathetic ophthalmia rarely followed. The condition might follow on cataract operations or iridectomy for glaucoma. The symptoms and signs were mentioned—dimness of vision, keratitis punctata, cloudy media, and formation of synechia. The indications for and against operation, and the determination of the suitable time for operation, would depend on the state of vision in the injured and in the sound eye, and on the signs of active disease. The medicinal or expectant treatment relied on atropine, mercurials, pilocarpine, and salvarsan. The theories of causation and pathology were mentioned in detail, and also the paths

of infection, and the theory of anaphylaxis. Special bacteria had an affinity for the uveal tract only, but the theory held by Brownlie and Hepburn that the disease was protozoal in origin was perhaps the most favoured.

##### *Clinical Cases.*

Dr. F. W. ROBERTSON showed: (1) A case of transposition of viscera in a man aged 25, with skiagrams in which the dextrocardia, displacement of the stomach to the right and of the liver to the left were clearly seen. (2) Psoriasis in a boy, aged 10, with a strong family history of syphilis. The distribution and character of the rash were unusual and the differential diagnosis was interesting. (3) Hydatid cyst of the meninges in a girl aged 15. There was a history of slowly developing right-sided hemiplegia followed by marked papilloedema on the left side. A diagnosis of cerebral tumour was made and an operation was performed, when a large hydatid cyst was found lying between the meninges of the parietal lobe on the left side. Papilloedema rapidly disappeared, hemiplegia passed off, but was not completely cured in the right arm. Fits occurred at nine months, twelve months, two years, and four years' intervals after the operation. During the current year fits had become more frequent and were definitely Jacksonian in type, beginning in the right foot. Skiagrams showed two spicules of bone evidently pressing on the upper part of the Rolandic area on the left side. The point in diagnosis was to decide whether the pieces of bone were the cause of the fits, or whether a patch of softening due to pressure was the focus. The question of treatment was discussed.

Dr. J. BORD showed: (1) A case of sarcoma of the sacrum in a woman aged 21. Four months previously a swelling had been noticed, followed by weakness and loss of sensation, in the right leg. Pain was severe and she was compelled to remain in bed; sedatives were administered. An operation was undertaken, but owing to haemorrhage was only exploratory in nature. Six intensive x-ray exposures had been given at intervals of one week. Improvement had been rapid and she was now able to walk; a small pigmented scar over the site of tumour was seen, but no tumour could be felt. (2) A case of bronchiectasis in a girl aged 16. She had been under observation for some weeks in a sanatorium, but all evidences of tuberculosis were wanting. The sputum was not fetid, due probably to good drainage from the site of disease in the right upper lobe. Physical signs pointed to the presence of a cavity. The physical signs eight years ago were apparently the same. The skiagrams were demonstrated by Dr. T. I. CANDY, and the differential diagnosis from a radiological standpoint was explained. (3) A case of eventration of the diaphragm, in a man 50 years of age, with vague pains in the epigastrium and in the lower half of the left chest, which he attributed to an accident seven years ago. A scar on the left side of the neck was referred to an operation for tuberculous glands. As the symptoms varied from time to time, skiagrams were taken of the chest and bismuth meals examined. Marked upward displacement of the stomach was seen. The question to decide was whether this was a case of eventration—namely, a diffuse relaxation of the diaphragm—or one of genuine hernia through one of the normal openings or through a rupture, possibly as a result of the accident seven years ago. The case was regarded as one of eventration, due to injury to the left phrenic nerve.

Dr. CANDY showed two cases to demonstrate further the value of x rays in treatment. (1) Lupus of the nose of four years' duration, completely healed with no scarring after three exposures. (2) An exuberant warty growth on the skin of the ankle, cured by six exposures of filtered rays at monthly intervals. A small pigmented scar remained at the site of growth. Photographs were shown of the condition before treatment.

##### *Syphilitic Aortic Aneurysm.*

Dr. P. C. INGRAM read a short paper on a case of syphilitic aortic aneurysm and regurgitation in a man 69 years of age, formerly a soldier. For three and a half years shortness of breath and pain across the front of the chest were the chief symptoms. An enlarged heart

was present with a to-and-fro bruit, but no abnormal cardiac dullness or pressure signs. The Wassermann reaction was positive. A skiagram showed an aneurysm of the aorta. Potassium iodide was given for three weeks and then nine injections of bismuth at weekly intervals. There was considerable improvement in the condition four months later; there was no chest pain, and the orthopnoea was less, but the urine showed a trace of albumin. A fortnight afterwards kharsulphan 0.3 gram and silversal 0.1 gram were started at weekly intervals alternately, but after the sixth he felt worse and colloidal iodine was given instead. Another course of nine injections of bismuth was given and further improvement noted. Three weeks later a slight attack of jaundice occurred. Thiostab was administered in five doses at weekly intervals and the jaundice had then cleared. The present condition of the patient was satisfactory, the pulse being 80 lying and 88 standing; the urine was normal and only slight dyspnoea and pain were experienced on exertion. The improvement under anti-syphilitic treatment was encouraging, but it was undertaken too late in the disease to be of very great benefit. The attack of jaundice illustrated the care required in the administration of arsenical preparations, and it would have been advisable in this case to have given kharsulphan only. The bismuth had been of benefit and had been well tolerated.

#### *Death following Wasp Sting.*

Dr. W. F. DONOGHY described two cases of wasp sting, one of which, in a man aged 44 and in good health, ended fatally. Sixteen years before he had been stung by a wasp and alarming symptoms developed. Recovery followed, but he had lived in dread of wasps since. In August last year he was again stung on the left forearm over the basilic vein. He quickly lost consciousness, cyanosis followed, there were jerky movements of hands, the tongue was swollen, and foaming at the mouth was seen. In a few minutes he was dead, before medical aid arrived. The interesting point in this case was the possibility of anaphylaxis or of suggestion playing a part; both might be responsible.

The meeting, which was well attended, terminated with a cinematograph demonstration by Dr. T. I. CANDY, who showed two films, the first of the capillary circulation as seen under the microscope, and the second of the social meeting of the Branch held in May at the Roman Amphitheatre at Caerleon.

## Reports of Societies.

### THE ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.

THE usual quarterly meeting of the Royal Medico-Psychological Association took place at the Horton Mental Hospital, and later at the West Park Mental Hospital, Epsom, on November 16th, under the presidency of Lieut.-Colonel J. R. LORD, C.B.E., M.B. A special meeting of the association was held on the previous afternoon in the Great Hall of the British Medical Association House to hear an address by Dr. ALFRED ADLER of Vienna on "The cause and prevention of neurosis," to which had been invited all psychiatrists and neurologists and senior medical students. There was a large attendance, and Dr. Adler was most cordially received and listened to with the greatest interest. We hope later to publish an abstract of his address.

Before introducing Dr. Adler, the PRESIDENT alluded, with deep regret, to the death of Professor Emil Kraepelin of Munich, an honorary member of the association since 1909 and a psychiatrist of world-wide reputation. The audience rose in silence as a tribute of respect and regret. At the meeting held at Horton Mental Hospital Professor G. M. ROBERTSON also referred to the death of Professor Kraepelin, and the PRESIDENT alluded with feeling to the passing of Dr. R. H. Cole, who had laboured so long and successfully for the association.

#### *A Research and Clinical Psychiatry Committee.*

THE PRESIDENT said that there had been a most encouraging response to his circular letter on this subject, and many helpful suggestions had been received. He expressed the view that every member should either have definite work to do for the association or some direct interest in it. Resolutions were unanimously passed appointing a preliminary Research and Clinical Psychiatry Committee to prepare the way for the standing committee on these subjects ordered by new by-laws under the charter; also regarding the establishment of divisional clinical meetings as outlined in the presidential address. The local authorities are to be approached to afford facilities for the holding of the latter (to which local practitioners will be invited) and to encourage all assistant medical officers to attend.

#### *Chronic Epidemic Encephalitis.*

At West Park Mental Hospital a joint paper by Dr. P. K. McCOWAN and Dr. J. S. HARRIS was read by the former on chronic epidemic encephalitis. It consisted of a description of what was being done for the cases of the condition in this institution, and of some experimental work with hyoscine, with special reference to its carbohydrate metabolism. The authors said that investigations in encephalitis lethargica were leading to a better understanding of the neuroses and psychoses, as it had afforded insight into the psychological and physiological mysteries of many mental mechanisms. The symptoms shown by some of the cases appeared first during an attack of acute epidemic encephalitis, and persisted after the disappearance of the other symptoms. It was found to be impossible to give a prognosis of the ultimate outcome of an acute attack, however mild—indeed, a history of an acute attack was not necessary to establish a diagnosis. In children especially later symptoms were common after an attack. Hyoscine could be regarded as a specific in the treatment of encephalitic Parkinsonism; therefore the authors first investigated the carbohydrate metabolism as represented by the blood sugar curve, experiments being conducted later on muscular tonus, and inquiry into the altered affectivity as shown by the psycho-galvanic reflex. All those phenomena were abnormal in these patients, but hyoscine caused them to approximate to the normal. In the normal person the subcutaneous injection of 1/100 grain of hyoscine hydrobromide was followed, in ten to fifteen minutes, by dryness of the mouth and throat, a sensation of giddiness and some mental confusion, slurring of speech, and inability to walk straight. There was also marked impairment of accommodation, so that none but the largest print could be read. Later there followed a feeling of laziness or fatigue, and if left to himself the person would fall asleep and remain asleep for several hours. So that, in the case of the normal person, the effects of hyoscine were depressant, the contrary effect to that seen in subjects of this disease. In practically every case of the disease under consideration a proper dose of hyoscine caused improvement; the general muscular rigidity was reduced, while the tremors of face and extremities and the excessive salivation and lacrimation disappeared. The patient's alertness was also increased, articulation was improved, and there crept into the rigid countenance some expressiveness. The action of hyoscine, the authors submitted, supported the thesis that the functions of the mind were dependent on the harmonious working of all parts of the body. The authors used an apparatus they devised for taking a mechanical record of the knee-jerks, and these records showed an approximation to the normal knee-jerk under the influence of hyoscine. A number of cases were related.

Discussing the disease in its general aspects, the authors said that the functional aura was here found to an extent not approached by any other group of patients in a mental hospital. They thought that here could be discerned a clue to the discovery of an organic basis for the so-called functional nervous disorders and psychoneuroses. In encephalitis lethargica there might be subtle biochemical or biophysical abnormalities. The site involved was that of the basal ganglia, a centre of prime importance in the instinctive and emotional life of man. The laboratory investigations were carried out at the Maudsley Hospital.

The effect of injecting 1/100 grain of hyosine was to depress the blood sugar values, but there might be a secondary rise of that curve due to some hyperglycaemia two hours after the glucose meal and the drug injection. A similar result was produced on the curve by atropine. These drugs also caused inhibition of the external secretion of the pancreas, and a general arrest of the secretions of the alimentary tract. The blood sugar values obtained in this disease were consistent with the theory that it was a chronic toxæmia. The results of the injection of hyosine simultaneously with the ingestion of glucose permitted of a classification of the cases into two groups: (1) those exhibiting Parkinsonism with a depression of blood sugar levels, (2) those not exhibiting Parkinsonism and in which the blood sugar curve did not show improvement after the injection. Hyosine could be given either subcutaneously or by the mouth, but the best effects followed a combination of the two methods, 1/100 grain injected in the morning, 1/50 grain during the day by the mouth. Some of the unpleasant effects were combated by giving 1/10 grain of pilocarpine. Some patients had been having hyosine two years, and no deleterious effects were traceable. The action of the drug was only temporary, and when it was discontinued there was a relapse into the former state. Stress was laid on the fact that these patients were still suffering from an active disease, not the mere after-effects of an acute process. The treatment, the authors said, must still be regarded as in the experimental stage. Two drugs were found very helpful for this disease—tryparsamide and argotropin. These were given to all cases, of both types. Tryparsamide seemed to gain access to the central nervous system in a way that no other arsenical preparation appeared to do, and no case had shown progress of the disease since it was given. The course was eight weekly injections of 2 to 3 grams.

Dr. HARRIS then demonstrated a large number of patients, illustrative of the various stages of the disease, in groups.

## TUBERCULOSIS IN MAN AND IN CAPTIVE WILD ANIMALS.

A MEETING of the Section of Comparative Medicine of the Royal Society of Medicine was held on November 24th, when a discussion on tuberculosis in captive wild animals as compared and contrasted with the disease in man was opened by Dr. H. H. SCOTT, pathologist to the Zoological Society of London.

Dr. Scott, in his opening remarks, dealt briefly with the question of the existence of tuberculosis amongst wild animals under natural conditions, stating that there was no evidence in favour of the occurrence of this. Taking into consideration the case of the more isolated native communities, it appeared that, on *a priori* grounds, it was most unlikely that tuberculosis should occur in free animals, though this was a difficult thing to prove.

The reasons for the readiness with which tuberculosis was contracted in captivity were in the main three. The first was the survival of the unfit, since the healthiest animals were killed or escaped, and it was mostly the sick, injured, or very young which fell into captivity. In the second place tuberculosis might result from contact, after capture, with man or other animals, while the wild animals were in a condition of susceptibility owing to the absence of previous immunization from such repeated doses of bacilli as were commonly found in civilized communities. Thirdly, the disease might be due to the confinement, lack of exercise, deficient sunlight, ennui, and in some cases inability to obtain their natural food. The various facts adduced were based on the findings and records of the necropsies performed on animals dying during the last two years at the Zoological Society's Gardens. It had been noticed that some of the animals dying with most extensive tuberculous mischief and a widespread distribution of lesions might exhibit practically no signs of ill health until a very few hours before death. This had been observed both in birds and mammals, and various illustrative examples were given. A cercopithecus at autopsy showed bronchopneumonic phthisis with pulmonary excavation and involvement of

the pleuræ, the omentum, and mesentery. The liver and spleen were thickly studded with caseating deposits; the head of the pancreas was occupied by a large tuberculous mass, both kidneys showed miliary tubercles, and the bronchial, infraclavicular, and mesenteric glands were enlarged, caseated, and softening. With so extensive a tuberculosis the animal was nevertheless not emaciated and had appeared to be in its normal state of health on the day prior to its death. In mammals and birds, but less so in reptiles, generalization of the disease was as a rule greater than in man, and the course seemed in most cases to develop much more rapidly. The difficulties of determining the primary portal of entry of the bacillus, by no means always an easy matter in man, were greater in animals because of the rapid development and generalization, rendering it sometimes impossible to say which was the oldest focus. Certain differences between the symptoms and also the pathological lesions in animals and in man were then detailed, notably the absence of hæmoptysis due to phthisis, which Dr. Scott had not seen in any of the animals, even in an advanced stage of pulmonary tuberculosis, and the rarity of tuberculous affection of the nervous system, or of the bones and joints. The only bones attacked with even relative frequency were the ribs, which, in monkeys, might be involved by direct extension from the lungs. On the other hand, in spite of the prolongation of the air passages into the long bones in birds, the bacilli, though repeatedly looked for, had not been found in the shafts even when the lungs and air sacs had been converted into masses of caseous tubercle. The rarity of pus formation in avian tuberculosis was mentioned and the possible relation of the Pierre Marie syndrome of hypertrophic pulmonary osteoarthropathy to tuberculous infection of the bones. The differences presented by tuberculosis in birds as compared with the condition in mammals were discussed in considerable detail, with particular reference to the nodular form and that known as "gelatinous tuberculosis," in which a hyaline necrosis seemed to occur simultaneously over an area of some size, as distinct from the slower progressive necrosis of mammalian disease. Another marked characteristic was the peculiar infiltrative form of avian intestinal tuberculosis. Brief descriptions were given of the microscopical differences between miliary tubercles in man, cattle, dogs, monkeys, birds, and reptiles. Specimens collected by Dr. Scott at the Zoological Society's prosectorium and now in the museum of comparative pathology at the London School of Hygiene and Tropical Medicine, were used to demonstrate some of the conditions described.

## TREATMENT OF CONGENITAL TALIPES.

A MEETING of the Bristol Medico-Chirurgical Society was held on November 10th, the President, Dr. A. L. FLEMING, taking the chair. After Mr. E. R. CHAMBERS had shown a case of recurrent carcinoma of the uveal tract in a woman of 55, and Dr. A. D. FRASER had exhibited specimens of endometrioma, Mr. A. W. ADAMS read a paper on the treatment of congenital club-foot.

Mr. Adams defined the differences between this condition and the deformities consequent on paralysis, spastic or flaccid. The etiology of congenital talipes equino-varus, the commonest variety, was unknown, but he inclined to the old theory that deficiency of the liquor amnii allowed pressure on the foetus. The theory of arrest of development could scarcely account for some of the varieties. The incidence was greatest among males; it was said to show a familial tendency, but this was found in two cases only of his series, who were brothers. There was a tendency to associated deformities, as illustrated by one case shown, with webbed fingers and ankylosed elbows, wrists, and other joints. The condition often affected both feet, and in his series this was found in half the patients. Two factors must be recognized; rotation inwards on an antero-posterior axis brought the os calcis up under the internal malleolus, while rotation inwards on a vertical axis at the mid-tarsal joint brought the fore part of the foot pointing inwards and the sole backwards. The tendons and ligaments on the inner side of the ankle-joint were shortened.

Treatment, to be successful, must begin early, at one month if possible, when the tissues were pliable and the bones relatively plastic; it must be regular, prolonged, and continuous. It was waste of time to attempt treatment on manipulative lines unless the parents realized that for success they must co-operate with the surgeon. For several weeks treatment aimed at reposition, for some months at retention, and for some years at education. The first step was to secure the reposition of the astragalus by manipulation around the antero-posterior axis. The astragalus was forced in under the tibia, and the os calcis was drawn downwards and outwards under the astragalus. In addition to forced movements by the surgeon, the foot was moved as far as possible in the correct position by the nurse several times a day, being held there for a few minutes. When the posterior part of the foot was rotated the anterior part was turned outwards on a vertical axis. Slight over-correction was the aim. In all cases some fibres of the deltoid ligament had to be divided, in many part of the inferior calcaneo-scapoid ligament, and in few was tenotomy needed. A diagram showed how a roll of stockinette might be used to avoid bruising. As soon as the foot could be brought well out it was put up in plaster for several weeks, with changes and manipulations once a fortnight. The tendency for the plaster to fall off a fat leg and foot was met by carrying it up over the knee or by incorporating strapping. The next step was tenotomy of the tendo Achillis; without this attempts to correct equinus would stretch the plantar ligaments. The over-correction should not be too great. A wooden sole-plate was used with strapping to retain the foot in the over-corrected position. Movements and massage were continued at regular intervals; this was the difficult time, for parents saw the foot in a good position, and wished to discontinue attendances, which had become wearisome. At 18 months a malleable splint down the back of the leg and along the sole was employed, fitted with a toe-plate to resist varus. The child was encouraged to walk, but wore the splint day and night; a small overshoe was used with the splint. The régime of massage and movements was continued long after the splint could be discarded. By the age of 3 the child could learn simple exercises, and so co-operate in treatment. In some cases, however, iron supports were needed for several years. In other patients who came late for treatment cuneiform osteotomy was required. The only absolute bar to success was failure to attend regularly for the necessary period of several years. Treatment might be interrupted by a variety of causes, such as illness of parents or patients, or by poverty. The stupidity or carelessness of parents might vitiate the results of months of work. Long treatment in plaster seemed to interfere somewhat with the nutrition of the limb. Neither this nor some degree of flat-foot (which was not rare) appeared to cause the patients any trouble. There was a tendency to hallux varus when the child began to walk without splints, and in some cases an inward twisting of the tibia; osteotomy of the tibia might be needed, but had not been employed for any of the cases shown. In conclusion, Mr. Adams classified in tabular form the results obtained with thirty-three feet, to indicate how regularly results less than "good" were associated with irregular attendance. Eight cases were shown to illustrate the later stages of treatment, and many photographs to demonstrate the application of various forms of retention apparatus.

Professor HENRY GROVES said that the greatest difficulty in treatment was to secure adequate co-operation by parents. He thought that insufficient emphasis had been given to the correction of the malposition of the astragalus. He had found that reposition in a small fat foot was not easy, but thought failures were often due to this part of the deformity not having been corrected. Where the foot faced inwards he advised osteotomy of the tibia. Tarsotomy gave excellent immediate results as regards reposition, but the after-treatment needed to be just as careful and prolonged, and the final result was not so good as with manipulative methods. He particularly admired the sole-piece used by Mr. Adams.

Mr. H. E. CHITTY agreed that the displacement of the os calcis was the most difficult part of the deformity to reduce. He had found plaster splints very difficult to

retain in position, and used a small internal malleable splint. In late cases he took out a wedge on the outer side to correct the heel; the remaining correction was easy.

Mr. E. WATSON-WILLIAMS had noticed that in the first case shown, and in several of the photographs, the second or third toe was pushed up out of line so as to lie on the dorsum of a neighbour. He asked about the correction of this, and suggested a connexion with the tendency to hallux adductus.

Mr. W. A. JACKMAN had obtained very good results in seven cases out of eight with Mr. Adams's splints, not using plaster; all his cases were bilateral.

The PRESIDENT believed the deformity was related to a defective heredity, which was relatively common in remote and isolated districts, and showed itself in mental as well as physical abnormalities.

Mr. ADAMS, in reply, said he recognized that the posterior deformity was the most difficult to treat. This correction could be made at the same time as the abduction, but it was easy to overdo it. In favour of plaster over splints at the early stage, he remarked that splints needed daily attendance. He admitted that the following up of cases would be made easier by the appointment of an officer for this service. Great efforts were often needed to keep some parents attending regularly.

### THE EVOLUTION OF GYNAECOLOGY.

At the first meeting of the eighty-fifth session of the Edinburgh Obstetrical Society, on November 10th, Professor R. W. JOHNSTONE delivered his presidential address on "The greater gynaecology: its relations to medicine and surgery."

Professor Johnstone recalled that the foundation of the society in 1840 was in the main due to younger members of the profession, who were practising midwifery and who were admittedly "dissatisfied with the position that branch of medicine held in the eyes of the profession and public, and who were anxious and determined to make an effort to raise it to a position more worthy of the important interests it guarded and the onerous duties it performed." Records of those days clearly showed that practitioners in obstetrics were looked upon by their brethren as being engaged in the practice of an inferior sort of art, which had little connexion with either medicine or surgery.

In seeking for an explanation of this alleged inferiority Professor Johnstone briefly sketched the history of midwifery, and indicated how the development of obstetrics was retarded by the practice of the art being in the hands of ignorant midwives. Little advancement was made during the fourteen centuries following the work of Soranus of Ephesus until William Harvey wrote his chapter on labour, the first original English work on midwifery. The Chamberlen family and their important discovery did much to drive out the uneducated midwife, who had been the sole attendant on the parturient woman for centuries, as no untrained woman could use such an instrument as the forceps on the living mother and the living child. Further advancement in the science and art of obstetrics was made during the next century, principally by Smellie, William Hunter, and Charles White, and it was due in the main to the teaching and influence of these great men that the practice of midwifery was finally transferred from the ignorant midwife to the trained male practitioner. The rapid development of the science of obstetrics after this transference had been accomplished showed what a retarding influence had been exercised during the long reign of the uneducated midwife. Surgery had suffered an eclipse similar to that of midwifery during the Dark and Middle Ages, and its elevation to equal partnership with medicine was a comparatively recent development, for which the genius of Paré, John Hunter, J. Y. Simpson, and Lister was required. Referring to the origin of the Edinburgh society, Professor Johnstone indicated how such a society could exercise beneficial influence, and how the Edinburgh society had been doing so. The development of obstetrical science and art during the last eighty-five years had been reflected at every step in the work of the society. Thus, in its annals were to be found the original papers on the

introduction of anaesthetics and their application to labour by the genius of J. Y. Simpson; the application of Lister's antiseptic principle to labour; the invention of rubber bags by Keiller, and their introduction into the uterus for induction of labour; the improvements of the forceps by the Simpsons, and later by Milne Murray, to mention only a few of the earlier papers. In the last thirty-five years the work of the society had shown no deterioration, and all the later discoveries had been fully discussed, and several had found origin within its precincts. Very important physiological and pathological research had been carried out by numerous Fellows of the society, perhaps the most important being the work of Matthews Duncan and of Hart and Barbour on the anatomy and physiology of labour, and the series of contributions by Ballantyne on ante-natal pathology. Gynaecology was not a recognized science when the society was founded, and it was not until the society had been in existence for twenty-five years that gynaecology emerged as a specialized branch of medical science and practice, the outcome of the work of both the surgeon and the obstetrician jointly. In their modern conception obstetric and gynaecology were inseparable as "the greater and the lesser" : it had been aptly said that good midwifery was preventive gynaecology, and until a considerably higher standard of midwifery was reached it would remain true that half of gynaecology was reparative midwifery. In this organic union midwifery and gynaecology were now intimately linked up with both medicine and surgery. To medicine they were linked by the recent developments of biochemical study of the maternal metabolism, of the toxæmias of pregnancy, and of the nutrition of the foetus; while the wide field of endocrinology was common to both medicine and the greater gynaecology. With surgery the greater gynaecology was closely linked by the numerous operations required to be performed, not only in gynaecology, but also in midwifery. The whole position had been summed up succinctly by Sir George Newman in his remark, "The obstetrician and gynaecologist is the great example of the unity of medicine and surgery in actual practice. Here is the full integration." Professor Johnstone pointed to the significance of such a remark being applied to the practitioner of what in 1840 was regarded as an inferior sort of art which had little connexion with either of the great departments of medicine or surgery. The Cinderella of medicine, as midwifery used to be called, had found her prince in gynaecology, and taken her rightful place in the family at last.

#### ROUTINE EYE EXAMINATION.

At a meeting of the London Association of the Medical Women's Federation, on November 9th, Miss ELIZABETH BOLTON, the President, in the chair, Miss IDA C. MANN read a paper on routine examination of the eyes as an aid to diagnosis.

Miss Mann said that by routine examination she implied such investigation as could be easily made by the general practitioner and would indicate any abnormality. The tests suggested were: Examination of the position and condition of the eyes and lids with the patient looking straight forward; examination of the movements of the eyes and upper lids when the patient followed a moving finger, the head being kept still; examination of the pupil reactions; rough test of the fields of vision with the hand; examination of the media of the eye and the fundus with an electrical ophthalmoscope, which would reveal the presence of opacities of the media and disease of the fundus without a mydriatic in most cases, though fuller examination might be necessary in order to establish the diagnosis. The electrical ophthalmoscope, being easier to use than the non-luminous instrument, should be in the possession of every general practitioner. The patient's visual acuity with each eye should be tested separately without glasses for distance and near vision; Snellen's and Jaeger's test types were the best for this purpose. Such a routine examination would in a large number of cases be found to afford most valuable assistance to diagnosis. In some instances it might even establish the diagnosis, as when it revealed, in a patient complaining of shooting pains in the legs, the presence of an Argyll Robertson

pupil; in other cases it would often indicate a fruitful line of investigation and treatment. Some patients complained of ocular symptoms only, others with symptoms elsewhere made no mention of their eyes. In some of the latter cases a direct question would elicit an admission of ocular symptoms, but in others, and these usually the more serious, the patient was quite unaware of the presence of any eye disease. In both groups an ophthalmic examination was equally imperative. In a certain number of cases, as for example, in errors of refraction, the ocular condition sufficiently accounted for the symptoms. Headache, not necessarily frontal, and often worse in the morning than at night, was a frequent accompaniment of error of refraction; it might be associated with depression, lack of concentration, fatigue, anxiety, and even, in some cases, nausea and dyspepsia. A suitable pair of glasses would benefit a hypermetropic clerical worker more than a month's holiday, and might often avert a definite breakdown; this was especially true in women between 45 and 50, at which age, unless she was myopic, the average woman would begin to suffer from eye-strain after close work. This onset of presbyopia was physiological, and, if corrected by glasses, not painful. If neglected, it could give rise to very severe headache, which, coming at a time of life when most women had been taught to expect a certain amount of discomfort, was often put down by them and their doctor to the climacteric, though inquiry would reveal that their periods were regular. A suitable pair of glasses for work would entirely remove the symptoms. It was much too common a practice to refer every pain in a woman of 46 to menstrual disorder, though evidence was accumulating to show that the menopause occurred on the average nearer 50 than 46. Men were, in her experience, much less tolerant of this presbyopic headache than women, and usually sought relief for it earlier. Much more important, however, than the detection of errors of refraction was the early diagnosis of glaucoma. Though not actually a matter for the general practitioner, since it demanded experience and a certain amount of elaborate apparatus, the disease could at least be suspected. It was accompanied by attacks of headache, transient blurring of vision, and, occasionally, nausea; the central visual acuity might remain good almost up to the onset of blindness. The acute form of glaucoma was most often overlooked by practitioners who did not perform routine examination of the eyes. Miss Mann mentioned the danger of injecting atropine before operation in a subject of chronic glaucoma, and quoted six cases treated for gastric influenza, intestinal colic, food poisoning and other troubles, before advice was sought for the ocular condition. In two cases the congestion of the eye was noticed by the doctor, who proposed to treat it when the patient was better, not realizing that the vomiting and collapse for which advice was sought could have been relieved immediately by a posterior sclerotomy, and the sight of the eye (which was in each case lost) probably saved. In other cases, the headache or other symptom for which advice was sought was a manifestation of a general disease having ocular signs; in these cases examination of the fundus was of much assistance in diagnosis. All cases of headache and vomiting required a fundus examination; a papilloedema would be found in some, and the diagnosis of cerebral tumour could be made before the onset of optic atrophy. In other cases the presence of disease of the retinal vessels, exudates, haemorrhages, patches of choroiditis, and other abnormalities would supply a diagnosis, or at any rate indicate a line of investigation, at an early stage. It was surprising how often the initial diagnosis of diabetes, albuminuria, arterio-sclerosis, and syphilis was made in the eye department of a general hospital. In disease of the central nervous system an ocular examination was pre-eminently of help, but a very large number of systemic and general diseases had ocular signs, and diseases so far removed from the eyes as apical phthisis and carcinoma of the pancreas might be suspected from an ophthalmic examination alone.

Miss Mann, in reply, said that an injection of eserine could be given before the atropine where glaucoma was suspected. She suggested that the circumcorneal injection mentioned by Dr. Casson might be related to a prolonged

effort of accommodation. She agreed that emmetropes often retained full power of accommodation long after the age of 45, but added that emmetropes comprised only about 1 per cent. of the population.

### FREQUENCY OF MICTURITION.

At a clinical meeting of the Newport Medical Society, on October 27th, the President, Dr. P. C. P. INGRAM in the chair, an address on frequency of micturition and its diagnosis was given by Mr. T. E. HAMMOND (Cardiff).

Mr. Hammond said that the desire to pass urine coincided with a sudden rise in the intravesical pressure, when the bladder held a volume which was fairly constant for the individual; moreover, when the urine passed over the prostatic urethra in the male and the female urethra, there was a reflex contraction of the bladder, and any change in this region was apt to set up a desire to pass urine. Consequently an increased desire was due to one of the following: increase in the volume of the urine after excessive drinking, in cold weather, in diabetes mellitus and insipidus, and also in chronic interstitial nephritis and hyperpiesia; in oxaluria and hyperacidity; interference with emptying of the bladder at the end of micturition by an enlarged prostate in men and by fibroids of the cervix, urethrocele, and a retroverted gravid uterus in women; conditions which prevented the bladder wall relaxing normally, such as lesions of the mucous membrane—congestion, inflammation, and ulceration; lesions of the muscle coat, seen in fibrosis after inflammation, and extravascular causes, such as ovarian cysts, large fibroids, and the pregnant uterus; lesions of the mucous membrane in the region of the ureteral orifices, the trigone and the prostatic urethra in men, and the urethra in women; irritation of the spinal centres in multiple and disseminated sclerosis and the crises of tabes. Reflex action had probably little effect; the frequency associated with renal colic and a calculus in the lower end of the ureter was probably due to the spasm of the ureteral muscle passing over and increasing the contraction of the bladder muscle. When the frequency was due to polyuria alone it was not accompanied by pain or urgency, and was evenly spaced throughout the twenty-four hours; if the bladder was involved some pain and urgency were often present. If after the completion of the action an equal amount of urine could almost immediately be passed it was due to a diverticulum, a stone, or the enlargement of the middle lobe of the prostate. With a lesion in the trigone or the prostatic urethra there was often an intense and urgent desire to pass urine repeatedly after the completion of the act. In examining the patient particular attention should be paid to the cardio-vascular and nervous systems; but even in the event of definite disease being detected here a careful examination of the genito-urinary tract was always essential, as marked cardio-vascular changes might be secondary to the enlarged prostate. X rays occupied a very secondary place to cystoscopy in the diagnosis of bladder lesions. Early diagnosis was of paramount importance in bladder lesions. It was sometimes found that though a lesion of the urinary tract, such as an inflammation, was cured, the frequency persisted owing to the scarring and fibrosis of the muscle, which remained after the original lesion had been cured. Frequency of micturition was not physiological in old age, but was always pathological, and should lead to careful examination of the cardio-vascular system and the prostate. Occurring in adults it should arouse suspicion of tuberculosis, and in doubtful cases a guinea-pig should be inoculated. It was never due to endometritis and was never cured by curetting. Endometritis was not infrequently associated with a chronic cystitis, and in such cases both were due to the same cause—namely, lowering of the general resistance; they were best cured by rest and fresh air. The practice of treating frequency by vaccino-therapy was to be condemned until an examination of the genito-urinary tract had negatived any associated lesion, since, even if bacteria and pus were present, these might be secondary to some lesion of the urinary tract, such as an enlarged prostate or stone. When neurosis was diagnosed the case should be reconsidered every three months, since early organic disease was difficult to detect.

### DISEASES OF THE HIP-JOINT.

At a meeting of the Aberdeen Medico-Chirurgical Society on November 4th, Dr. JAMES CROMBIE, the President, in the chair, Mr. ALEXANDER MITCHELL gave a demonstration of lantern slides illustrating diseases of the hip-joint.

Mr. Mitchell said that the future of a patient suffering from an affection of the hip-joint was greatly dependent upon an accurate diagnosis and a real understanding of certain well established principles of treatment. A periodic review of the methods of treatment must be beneficial to all if such conditions as great shortening and loss of function were to be avoided. In dealing with the subject of tuberculous lesions of the hip-joint, Mr. Mitchell emphasized the fact that in cases, if at all severe and accompanied by bone destruction, there was a persistent tendency for the head of the bone to become dislocated, which condition, left untreated, resulted in shortening of the limb even up to four inches. Fixation of the limb in a fully abducted position with extension prevented this slipping out of the head, and, combined with treatment along modern lines, a cure of the disease would result with probably impaired movement, but with little shortening and subsequent disability. Unless this dislocation, which so readily occurred, was thoroughly understood, even the most careful treatment would not produce the desired result. Many difficulties arose in the treatment of these cases, but they must be overcome if the patient was to get the results which might reasonably be expected at the present day. These difficulties, such as proper fixation and special nursing, could be overcome to a great extent by prolonged institutional treatment and careful observation afterwards. In referring to modern methods of treatment, tribute was paid to the pioneer work of the late Hugh Owen Thomas of Liverpool and to Sir Henry Gauvain and Dr. Rollier. An excellent series of slides was demonstrated, including tuberculous lesions, osteo-chondritis deformans juvenilis, fibro-cystic disease, coxa vara, congenital dislocation, malignant disease, osteo-arthritis, and fractures of the neck of the femur in old people. A plea was put forward for the more active treatment of fractures of the neck of the femur in the aged.

### MEDICAL CRIMINALS.

At a meeting of the Brighton and Sussex Medico-Chirurgical Society, on November 4th, an address on some well known medical criminals was given by Dr. L. A. PARRY.

Dr. Parry said he would not deal with such famous medical poisoners as Palmer, Pritchard, and Lamson, but rather with less widely celebrated instances. His first example was that of Dr. Warder of Brighton, who, in 1866, poisoned his wife by means of aconite, and then, when suspicion was aroused, himself took prussic acid. Two previous wives had died in suspicious circumstances, and there was very little doubt that he had also poisoned these. The case aroused very considerable interest at the time. Dr. Alfred Swayne Taylor, who examined the viscera, said he was unable to find any poison, although he had carefully tested for all the well known alkaloids, including morphine, strychnine, and aconitine, and that injections from the organs into a rabbit had had no harmful effect; yet after hearing the evidence of the victim's medical attendant he was of opinion that aconite poisoning was the cause of death, and the jury returned a verdict to that effect. Warder had been a lecturer on forensic medicine at the Grosvenor School, adjoining St. George's Hospital, and was one of the many members of that school who gave evidence in favour of Palmer, the infamous poisoner. The judge at Palmer's trial had made some rather scathing remarks on these witnesses, blaming them for being advocates determined to prove the innocence of the prisoner rather than medical witnesses. Dr. Parry mentioned various other cases of poisoning by doctors, including Smethurst, who bigamously married a lady and then killed her for her money. He was convicted and sentenced to death, but, owing to a mistake made by the Government analyst, doubt was cast on the justice of the verdict and the Home Secretary took the unprecedented course of referring the whole of the evidence to Sir Benjamin

Brodie, and, as in his judgement there remained a slight doubt, Smetthurst was pardoned and released. He actually brought an action in the courts to obtain the money of the wife he had murdered, and won his case. He was afterwards sentenced to a year's imprisonment for bigamy. Another instance was that of Dr. Cross of co. Cork, who fell in love with the beautiful and accomplished young governess of his wife. She yielded to his solicitation, and as he was most anxious for a legal union, he murdered his wife by means of arsenic, and at once took the girl to London and secretly married her. Suspicion was aroused, the body was exhumed, and arsenic found. This led to the speedy trial, conviction, and execution of Cross. Some examples of medical men who had been charged with high treason were then given. Dr. Cameron, in the rebellion of 1745, was medical officer in charge of troops, and after the battle of Culloden escaped to France. Most of those who had taken part in the rising were pardoned, but an Act of Attainder was passed excluding certain persons, among them Cameron, from this indemnity. Some eight years later Cameron returned to his native land; he was arrested and hanged as a traitor. Dr. Watson, who engaged in the political upheavals after the end of the Napoleonic wars, and was connected with the notorious Thistlewood (later executed for his share in the Cato Street conspiracy), was one of those who led the mob which set out to burn the Tower of London, the Bank of England, and other Government buildings; although this object was not attained, great damage was caused by the rioters. Watson, mainly owing to the very brilliant speech of his counsel, Mr. Wetherell, was acquitted. After the battle of Sedgemoor the Government, not satisfied with the cruel and vindictive treatment of the rebels by Judge Jeffreys, arrested Dr. Bateman and charged him with high treason. Bateman was a strong supporter of the Exclusion Bill, and had rendered assistance to Titus Oates when that rogue was whipped in the streets of London; he was convicted of complicity in the Whig plot and sentenced to be hanged and quartered. Dr. Parry pointed out that this short list by no means exhausted the doctors who had been entangled in political affairs, and who had been charged with high treason or other serious offences. Others were Dr. Wakeman, physician to Queen Katherine, Dr. Bastwick, Dr. Spruell, Dr. Hensey, Dr. Sheridan, and Dr. Joseph Collier. Two cases of murder by violence by medical men were recalled: that of Dr. Levi Weil, who turned burglar and murdered a man in one of the houses he robbed, for which he was hanged; and Dr. Smith of Aberdeenshire, who killed a labourer after heavily insuring his life, but was acquitted.

## DIAGNOSIS AND TREATMENT OF GONORRHOEA.

COLONEL L. W. HARRISON opened the session of the Medical Society for the Study of Venereal Disease on November 26th with a survey of modern methods in the diagnosis and treatment of gonorrhoea.

He emphasized the need for laboratory procedures to determine the nature of an infection. Those who neglected microscopical examinations of the secretion often went on treating for weeks a non-gonococcal infection with potassium permanganate or one of the endless varieties of silver preparations, which, in his judgement, were useless against such organisms as *B. coli*, *streptococci*, and *staphylococci*. There were differences of opinion as to the value of cultures in the diagnosis of gonorrhoea, but personally he thought them indispensable in female cases, and often valuable in male urethritis. While he did not think the complement fixation test as satisfactory as the Wassermann in syphilis, it was carried out as a matter of routine in all the female and many of the male cases attending his clinic. On occasion a positive reaction by this method was the only indication that a gonococcal infection had not been eradicated. As for topical diagnosis, Colonel Harrison said that he was not greatly concerned, in the acute stage of gonorrhoea, to determine whether or not a patient had posterior as well as anterior urethritis. It did not affect the general lines of his treatment, because he believed in washing the whole urethra with mild lotion from the first. It surprised him to see

those who limited local treatment to the anterior urethra until they considered the posterior urethra affected rely for the diagnosis of commencing posterior urethritis on the two-glass test, because a little thought must convince them that, when the posterior urethra began to secrete pus, all of it must be washed into the first glass. He also urged the value of the urethroscope in diagnosis; to omit its use seemed to him reactionary. With regard to treatment, he was one of those who, while not denying the value of local treatment, did not believe that there was any bactericidal remedy which could reach down to and destroy the gonococci in the depths of the tissues. He sought to cure gonorrhoea by encouraging those processes whereby the tissues rid themselves of the infection. The modern treatment of gonorrhoea consisted in the application of two great surgical principles—namely, the raising of the patient's resistance and the securing and maintaining of drainage. Silver nitrate was formerly the great stand-by in both male and female gonorrhoea, and it was still used by many workers in female gonorrhoea in strengths which, in his view, only cauterized the surface, converting it into an excellent medium for the growth of secondary organisms, and left considerable scarring, whilst failing to kill the deeper-lying gonococci. The ineffectiveness of silver nitrate as a complete cure was sufficiently shown by the use of the innumerable other silver preparations which, during the last thirty years, had been advocated in its stead. He was in agreement with many workers who were trying to discover indirect methods of assisting the tissues to eliminate the gonococci. Some workers believed that vaccines had a specific value, and others that any good effect was by virtue of their protein-shock action. Colonel Harrison himself had always held that there was somewhere in certain cultured strains of gonococci the means of raising the patient's resistance to a degree sufficient to bring about the elimination of the infecting organisms. On the value of protein-shock therapy in gonococcal infections, he could say only that it was certainly useful in complications, but that here, as in vaccines, there was much still to be learned as to preparations and their dosage which gave the best results. At St. Thomas's they had used chiefly electrargol and milk. The results with milk in combination with vaccine had not been so good as those claimed by Tansard, possibly because the milk was not so full of bacteria as that used by the French worker. In diathermy at St. Thomas's the results had been sufficiently encouraging to justify perseverance. He believed that it acted, not by destroying gonococci by heat, but probably by an auto-vaccine effect.

Major E. C. LAMBEIN described in detail certain investigations, not yet completed, which are taking place at the Royal Herbert Hospital at Woolwich on the scientific preparation of a vaccine against gonorrhoea. The results so far obtained indicate that gonococci can be divided into good and bad immunizers, and that from the former can be split off a fraction which is antigenic but not toxic.

## JAMES MACKENZIE INSTITUTE.

On November 3rd Dr. BARCLAY NESS communicated a paper on "Difficulties in the clinical diagnosis and prognosis in the various forms of chronic Bright's disease." After giving a classification of the pathological changes found at death, he showed that mixed or transitional forms of disease were common, and that while the diagnosis of the pure types of lesion could be made with fair certainty during life, the difficulty of accurate diagnosis of the transitional forms was considerable. He discussed in detail the clinical phenomena upon which the differentiation might be made, and commented specially upon the fact that some of these had obviously been in existence for months or years before giving rise to definite symptoms, since the patients often presented themselves in the first instance with the disease fairly advanced. In hospital practice the "secondary contracted kidney" was the commonest form of chronic Bright's disease encountered, while the "primary granular contracted kidney" was comparatively rare. He emphasized the importance of the information to be derived from ophthalmoscopic examination of the retina.

## Reviews.

### ULTRA-VIOLET LIGHT.

ONE of the most satisfactory features of the more recent books on ultra-violet therapy is that they are becoming increasingly practical and begin to record the results of clinical experience. Dr. BELL FERGUSON's little book on the *Quartz Mercury Vapour Lamp*,<sup>1</sup> which is none the less valuable because it deals with a single type of illuminant only, can safely be recommended to anyone who desires a good practical introduction to ultra-violet light therapy. His notes on the historical and purely physical side of the subject are clear, concise, and interesting, and are illustrated by a chart of the whole range of electro-magnetic waves. These waves vary from the gamma rays, which have a length of about a ten-millionth of a millimetre, up to the waves employed in wireless work (and waves even beyond those), which have a length of 2,000 metres and more. Between the two extremes are  $\alpha$  rays, the ultra-violet rays, the visible light rays, and the infra-red or heat rays. To those who are comparatively untutored in the mysteries of modern physics, this chart, which was originally made by the Royal Society for the Wembley Exhibition, gives a concise picture of the nature and powers of all the different varieties of electro-magnetic radiations. The more important section of the book is, of course, that devoted to the use of the mercury vapour lamp and the results achieved with it. Dr. Bell Ferguson recommends that made by Messrs. Kelvin, Bottomley and Baird; in it there is no vacuum, and it is more constant in output and of longer life than the types in which a vacuum is present. Moreover, it is of British manufacture. He gives full details of the methods and dosage employed by himself in various types of case, both as regards the length of exposure, the distance of the patient from the lamp, and whether general or local irradiation is preferred. In fact, after reading this book with care, any practitioner could safely begin to use ultra-violet light in treatment, and we think that this is the best testimony that can be given to its value. In addition, it may be added that although the author is obviously keen on the subject, as is proper, he makes no extravagant claims for the healing powers of ultra-violet irradiations, and gives a scrupulously fair account of his own experiences in their use. The book is fortified by a preface by Sir Henry Gauvain, who is well known as one of the pioneers, in this country at all events, of light treatment in surgical tuberculosis, and who cordially recommends the work to the medical public.

Although, as has been implied above, ultra-violet light has become increasingly popular in this country during the last three or four years, it will come as a surprise to many that since 1907 it has been in use in Germany for the treatment of baldness, with results undoubtedly worthy of serious consideration. Dr. NAGELSCHMIDT, whose book first appeared in 1913, has collected in a new edition<sup>2</sup> 200 cases, all treated locally with ultra-violet light. He excludes 43 of these from his statistics as the knowledge of their subsequent history is insufficient, but of the remaining 157 he gives details: 104 of them were cases of alopecia areata, of every degree of severity; 80 he claims as cures, 16 as showing improvement; in 8 the condition, he admits, was unchanged. He succeeded even in curing 6 cases of total alopecia, and out of 18 such cases only 4 were entirely unaffected by the treatment. Perhaps the most striking of his results are those he claims for the 53 cases of seborrhoeic alopecia; all are stated to have been cured. As this is a disease which is the cause of the common type of baldness in men, the gradual thinning and disappearance of the hair over the crown and temples, our interest was naturally aroused, and we hoped that baldness (which is known even among

dermatologists) would soon become a thing of the past. Examination, however, of the details of the cases given dashed our hopes. Many of the patients were females, in whom the affection seldom leads to denudation of the scalp; others were described as cured owing to the cessation of scaling and irritation of the scalp; and as regards the hair itself the report was merely that it was "essentially thicker." Consequently we came to the conclusion that although in all probability benefit is to be derived from the use of ultra-violet light in such cases, it does not provide the specific cure which is desired. Dr. Nagelschmidt uses a quartz mercury vapour lamp, air-cooled, of a type which is now familiar in this country, made by the quartz lamp company of Hanover. For directions as to the time of exposure, precautions to be taken, the interval to be allowed between the sittings, and other details, we must refer the reader to the original. Ultra-violet light is now well established as a treatment for alopecia areata, and it probably deserves to be employed more often in the treatment of alopecia of the more ordinary type. Dr. Nagelschmidt is a pioneer in this field, and we are indebted to him for providing an account of his methods which will enable others to follow them.

In *Sunlight and Artificial Light*<sup>3</sup> Mr. HAROLD WIGG gives a short and simply written exposition, intended for the use of nurses, of the nature of ultra-violet rays and of their application in the treatment of some diseases. The descriptions are given in clear, though occasionally flowery, language, and a few figures and illustrations help the reader. Mr. Wigg states that light is a potent drug which cannot be used indiscriminately without danger. He deprecates also the tendency to regard light as a panacea for all evils. We note, however, that advertisements in the booklet urge the reader to have the magic of the sun-bath in his own home at the cost of less than 2d. a bath.

### EPILEPSY.

Drs. R. G. ROWS and W. E. BOND have written a volume entitled *Epilepsy: A Functional Mental Illness*,<sup>4</sup> which, as its subtitle suggests, seeks to develop the thesis that the various symptom-complexes to which the term "epilepsy" is usually applied are determined by previous psychic occurrences with strong emotional colouring. On the basis of such an etiology the authors deprecate the use of drugs, and advise a simple life, the avoidance of strain and excitement, and psychotherapeutic measures consisting of explanation, exploration, and re-education.

We cannot but feel that much more evidence in support of this theory than appears in this volume is required in order to make it convincing. The conclusions reached are based largely upon the study of "shell-shocked" soldiers, and in these cases it was only to be expected that the study of the psychic content should reveal the existence of unpleasantly toned emotional complexes. It is quite conceivable that the terrible experiences of these patients were in a measure instrumental in the production of epileptic manifestations. Further than this it would seem difficult to proceed with the authors in their attempt to formulate a general theory of epilepsy. Furthermore, though a psychological understanding of the epileptic is necessary for the carrying out of treatment, drugs are often unquestionably of considerable value. Many epileptics, whose lives are rendered almost useless by the disease, are able to mix with their fellows and earn their living under a suitable drug régime.

In the preface to this volume Dr. Bond explains that at the time of the death of Dr. Rows this monograph was "in the rough," and that he was placed in a difficult position by the loss of the co-operation of his colleague. We are grateful to him for publishing this work, not only because it contains a number of interesting discussions and observations, but also because it affords an opportunity of paying some slight tribute to the work of his collaborator. Dr. Rows was responsible for much notable research in the

sphere of neuropathology before the war, and the value of his unsparing and devoted work on behalf of the war-shocked soldier, both during and after it, can scarcely be overestimated.

### THE PROTEINS.

IN *Chemistry of the Proteins, and its Economic Applications*,<sup>5</sup> Dr. DOROTHY JORDAN LLOYD offers us a very useful little monograph, though we suspect that she is more in sympathy with the chemistry of her subject than with its industrial aspects.

It has been the habit of some teachers to treat the proteins as a race apart, undisciplined to the conventions of molecular behaviour. True, they are built of the same clay as other substances, but their peculiarities of conduct are held to betray an unnatural unbringing. For this view there is reason enough in the idiosyncrasies of protein behaviour, but the regrettable consequence has been that this group of compounds has not, on the whole, been seriously treated by the organic chemist. It has been the privilege of the last few years to show that an enlightened use of physico-chemical precept, building upon the solid analytical foundations laid by the masters of biochemistry, could tutor many of the vagaries of protein behaviour to classical conventions. The story is well, but not exhaustively, told by the author, who thereby gives us—what we had lacked—a monograph in our own tongue on the position of protein chemistry in its analytical, synthetic, colloidal, physico-chemical, and applied aspects. The balance is, on the whole, well maintained, and a student, baffled by the elusive treatment of the subject in many general textbooks on chemistry, should derive real satisfaction from this work.

Phenomena are not always so abstruse as the labels that are fixed to them, and—as this book shows—a considerable understanding of much in the behaviour of proteins may be achieved without great subtlety of argument or ingenuity of nomenclature.

### RENAL SURGERY.

F. MCG. LOUGHNANE has written *A Handbook of Renal Surgery*<sup>6</sup> for the use of students and practitioners, and has aimed at presenting in as concise a manner as possible a complete up-to-date statement of practical renal surgery. The title of the book is, however, somewhat misleading, for far more space is given to diagnosis and methods of examination than to treatment. Indeed, it is not so much a handbook of renal surgery as a guide to modern methods of diagnosis, and particularly to pyelography. The subject matter is illustrated by numerous pyelograms which must go far to convince any reader who is not acquainted with the refinements of modern methods of diagnosis of what great advances have been made within the last ten years. In addition to the pyelograms, the book contains some excellent pictures of the kidney after oxygen inflation of the perirenal tissues. The text accompanying these radiographs is written in a clear concise style and is eminently practical in its outlook. As stated above, the signs and symptoms of renal lesions have been discussed in Mr. Loughnane's book with far greater thoroughness than the methods of treatment applicable to these conditions. It is indeed in his handling of renal surgery treatment that a certain loss of proportion is apparent when the aim of the work is borne in mind. Quite apart from such statements as that in hydatid disease "an attempt should be made to remove the cyst *in toto*," a piece of advice with which most people who have had to deal largely with echinococcus of the kidney will probably quarrel, the operative surgery of the kidney has been dealt with so briefly that the work cannot serve as a guide to treatment. Though the book falls short in this respect, what it says is sound, well written, and well illustrated.

<sup>5</sup> *Chemistry of the Proteins and its Economic Applications*. By Dorothy Jordan Lloyd, M.A. Cantab., D.Sc. Lond., F.I.C. Introduction by Sir Frederick Gowland Hopkins, M.D., D.Sc., F.R.C.P., F.R.S. London: J. and A. Churchill. 1926. (Post 8vo, pp. xii + 279; 48 figures. 10s. 6d. net.)

<sup>6</sup> *A Handbook of Renal Surgery*. By F. McG. Loughnane, F.R.C.S. London and New York: Longmans, Green and Co., Ltd. 1926. (Demy 8vo, pp. xiv + 210; 46 figures. 10s. 6d. net.)

### THE CONTROL OF CANCER.

*Cancer, its Control and Prevention: A Book Everyone Should Read*,<sup>7</sup> by the late Dr. HALL-EDWARDS, is a small volume intended to give the public what ought to be common knowledge with regard to cancer, an ignorance of which is responsible for a preventable shortening of the lives of a large number of persons. The author emphasizes two directions in which there is room for improvement—namely, an earlier application for treatment than is frequently the case, and the avoidance of recognized causes of cancer. With regard to the first point, a patient cannot be expected to appreciate the grave significance of many apparently trivial symptoms. The problem is to educate him to recognize what symptoms he must not regard as trivial until he is confirmed by medical authority. With regard to the second point he has to be taught to realize the importance of irritation as a factor in the causation of cancer, and to know the common forms of irritation that should be avoided or not allowed to continue. Dr. Hall-Edwards's book supplies much information on these matters; he considered that the objects aimed at could be best attained by means of a vigorous propaganda. He suggested measures on the lines of the campaign of the American Cancer Control Committee, and expressed a hope that the Ministry of Health might authorize the formation of similar committees to undertake the propaganda. The American committee favours propaganda through the daily press; we are inclined to think, without any desire to prejudge the question, that in this country the daily press would not be a suitable agency for the purpose. It is difficult to formulate a practicable scheme, but it seems that, even with the existing organization, more might be done than is done by that large body of practitioners who may be called "family doctors." It is probable that they could be very helpful in drawing their patients' attention to the matter and gradually inculcating the habit of bearing it in mind. It would seem to be an important part of preventive medicine, and falls well within their sphere.

### MONGRELS.

MESSRS. ARTHUR H. ESTABROOK and IVAN E. McDONOUGH's book *Mongrel Virginians*<sup>8</sup> is a study of descendants of four men—one a white, the others Indians—who settled in the foot-hills of a mountain range in Virginia. There was much subsequent intermixture of blood with negroes and Indians, and the group has experienced the social ostracism to be expected in a society where colour is a class distinction. A result has been that matings tended to be frequent within the group; in the fifth generation 58.6 per cent. of the matings were within the family, in the sixth generation, not yet completely paired, 37 per cent. of the unions have been consanguineous. The group consequently presents many of the characteristics of a separate community, and this book is a detailed record of the characteristics of the individuals, followed by a brief statistical summary of the results and their interpretation.

Reviewers are often accused by disgruntled authors of not reading the books criticized. This reviewer must confess that he has only read a small proportion of the 130 pages devoted to individual descriptions, of which the following is a typical specimen:

"Oneida, the last of this fraternity, born 1896, light in color, has little education, and has been a prostitute for some years. She has had two illegitimate children, one by Lloyd Jones, now with its father, and 'B,' 'of mixed blood,' who died in 1914, soon after birth, from what was supposed to be mumps. She is 'no good.'"

Even the life stories of the many bold bad women, such as Abigail, who, although never married, wears two huge brass wedding rings and has borne eight illegitimate children, or Hepsy, who was a "promising girl" "when

<sup>7</sup> *Cancer, its Control and Prevention (Education will Lower the Death Rate): A Book Everyone Should Read*. By John F. Hall-Edwards, L.R.C.P., L.M. Edin., D.R.M.E. Cantab., F.R.S. Edin. Birmingham: Cornish Brothers, Ltd. 1925. (Cr. 8vo, pp. 84. 2s. net.)

<sup>8</sup> *Mongrel Virginians: The Win Tribe*. By Arthur H. Estabrook and Ivan E. McDonough. Baltimore: The Williams and Wilkins Company; London: Baillière, Tindall and Cox. 1926. (Cr. 8vo, pp. 205; 21 illustrations. 13s. 6d. net.)

young," but "became a prostitute when in her youth" (a subtle distinction, this, between being young and in one's youth), and "has an ugly temper which she uses occasionally, especially towards her mother," are not deeply interesting, and one hastens to the conclusions. They are these: that the whole tribe is below the average, mentally and socially, and that, considering the remoteness of pure Indian blood, the persistence of Indian traits among them is remarkable. "When one sees a group of men walking along the county road they will always be found parading in single file and for the most part non-communicative." The authors infer from their rather meagre statistics (125 reproducing females) that the fertility of the group is above average, but without a comparison with agricultural families from the same part of the country this conclusion cannot be accepted as proven. The authors also seem to hold that the data are evidence against the social expediency of mixed marriages. "But in speaking of one of the unsocial traits of the group they remark that "this may be largely due to their geographical and their even greater psychological isolation throughout life." Altogether apart from any biological considerations, one would not expect a socially ostracized minority to score high marks when examined by the standards of the majority.

This book represents a great deal of work, and is, let us hope, of scientific value. But its authors do not display much literary skill, and, since to present their case readably would require great literary skill, the book is not easily readable. These are raw materials rather than a finished product.

### SURFACE CHEMISTRY.

It is well known that the surface of a solid or liquid exhibits properties which belong to the surface alone, and are not shared by the interior part of the substance. Dr. E. K. RIDEAL's *Introduction to Surface Chemistry*<sup>9</sup> treats of the effects taking place at the surfaces which separate contiguous bodies dealing with them as functions of chemical constitution. The purely physical properties of surfaces have been the subject of research since the early days of experimental science. More recently many of the known phenomena have been co-ordinated and interpreted in terms of the reciprocal chemical relationships of the participating substances. The examination of such relationships has now been so far extended in this sense that a basis is afforded for the explanation of all that takes place between matters which do not destroy each other's identity on contact.

The study embraces the primary causes leading to the formation of emulsions and colloids, and enters into adsorption and its attendant phenomena of catalytic activity. The nature of the effects induced at the interface of contiguous matters being determined by the forces exerted on the individual molecules or by the energy they possess, the ultimate explanation of their behaviour is resolved into a consideration of these terms. The study is thus a branch of molecular physics having a special regard to chemical effects. It is therefore necessarily given a mathematical treatment. This fact need not prove a serious obstacle to the ordinary reader. The mathematical expressions are not generally beyond the reach of the student of physics and chemistry; they are nowhere an embarrassment, and the text supplies an adequate introduction to the basic facts and their consequences. Dr. Rideal's treatment of the subject is systematic; it is set on a broad basis dealing with many aspects of the various problems. The book is ostensibly prepared for those beginning their acquaintance with the subject, and is written, we are happy to note, with a measure of sympathy for their powers of perception, for we have not infrequently seen a style in textbooks much like that of a candidate writing for his examiner, and presenting a context sufficient to demonstrate the writer's knowledge but not well suited to enlighten the uninformed. This book is one of the first, if not the first, to make of the subject the special study which it is destined to become. There is hardly a branch of knowledge that does not owe

some debt to research on the behaviour of the single molecule, and particularly its behaviour when it occupies a place at the surface of the body to which it belongs. It would be safe to say, for example, that nothing is known of lubrication save what is revealed by surface chemistry. Physiology and a number of other sciences must become more and more directly dependent on what is taught by the facts and theories of this special province. Dr. Rideal has prepared a useful book, which must become a necessary part of the equipment of every scientific reader.

### NOTES ON BOOKS.

THE third number of this year's volume of *the Annals of Medical History*<sup>10</sup> has on the cover a portrait of Sir William Lawrence (1783-1867), that commanding personality, and orator who was on the surgical staff of St. Bartholomew's Hospital for fifty-two years (1813-1865). The account of his life, taken admittedly in part from Sir Norman Moore's *History of St. Bartholomew's Hospital*, has special reference to his ophthalmic work. The frontispiece, representing the first Alexander Monro, illustrates an editorial article on the early teaching of anatomy at Edinburgh, based on an article published some four years ago by Dr. J. D. Comrie. The account of John Redman of Philadelphia contains the history of the founding in 1786 of the College of Physicians, of which Redman was the first president. In a scholarly article redolent of much research Dr. C. G. Cumston traces the history of herpes from the time of Hippocrates to the early years of the nineteenth century. Dr. Roy L. Moodie's account of an alveolar abscess in the mandible of a rhinoceros belonging to a group of running mammals which have been extinct probably for millions of years is of special interest in view of the rarity of dental disease in fossil vertebrates. Dr. W. G. Aitchison Robertson's article on the use of unicorn's horn, coral, and stones in medicine discusses the origin of the unicorn myth. Other articles in this number are on the teachers and textbooks in use during the thirteenth and fourteenth centuries in Paris, on Pepys's account of the plague, on Bernard de Mandeville's "Fable of the Bees," and on the operative story of the heart.

*What it Feels Like*<sup>11</sup> is an attractively written series of letters to a medical friend by "Doctor Robin," who has plenty of breezy humour, and, indeed, does not take himself very seriously, for after his degree and diploma on the title-page he adds: "Holder of the usual sort of hospital appointments, and author of the usual unimportant treatises." His description of the life of a medical missionary in China covers the five years ending February, 1925, and breathes a wholesome muscular Christianity and genial charity. The account of the varied life and wide opportunities for medical work in the Chinese mission field should make recently qualified readers in search of a career consider such a life, when the present troubles in China have passed away.

The twenty-second volume of *The Ophthalmic Year Book*<sup>12</sup> contains bibliographies, digests, and indexes of the literature of ophthalmology for the year 1925. The information is arranged under anatomical, physiological, and pathological headings, and each reference is accompanied by a short abstract of the book or article concerned. Good indexes of authors and subjects are appended, and ophthalmic surgeons will find this a most valuable key to recent work in their specialty.

*The Motor Electrical Manual*,<sup>13</sup> which has reached its third edition, essays the difficult task of explaining to the owner-driver the electrical contrivances upon which the running of his motor car now so largely depends. Elementary explanation of electrical principles is given in sufficiently non-technical language, together with the information required for maintaining the working of the equipment. Some of the statements made are perhaps not quite forcible enough; thus, to say that "it would not be possible to . . . use 6-volt bulbs on a 12-volt equipment" hardly conveys a full impression of what would result from the attempt.

## British Medical Journal.

SATURDAY, DECEMBER 4TH, 1926.

### HARVEY'S INFLUENCE IN EDINBURGH.

THIS issue of the JOURNAL opens with the oration recently delivered by the President-Elect of the British Medical Association, Sir Robert Philip, on the occasion of the Harveian Festival of the Edinburgh Harveian Society, which has flourished for a century and a half. In his interesting and graceful outline of the life of Harvey, Sir Robert suggests that in his capacity of Physician Extraordinary to King James he might have come into contact with Shakespeare, who was a Court servant. The possibility of this relationship is undeniable, but there is no available evidence one way or the other. William Harvey, equally with William Shakespeare, was not for an age but for all time, and not for one country but for "states unborn and accents yet unknown"; and Edinburgh and the Scots, ever hungry for the fruits of the spirit, have done well to honour the founder of modern physiology. When we look back on the careers of the physicians of the sixteenth and seventeenth centuries we realize how international science then was. The Italian universities welcomed scholars from all parts of Europe, as did the Dutch schools of learning, which were especially frequented by the Scots. The familiarity of all educated men with the Latin language, which they learnt and used as a living and not as a dead tongue, rendered this intercourse and international understanding easy. Latin came as readily to Harvey's tongue and pen as French does to a modern diplomatist, and very little by him is extant in any other language.

Small wonder that Edinburgh should have its Harveian Society, although all records of the personal influence of Harvey in that city are lost. We know that in 1633 he accompanied his royal master on his visit to Scotland, and it cannot be doubted that his inquiring mind led him to seek out all or any of the Scottish physicians who had pretensions to scientific attainments—if, indeed, as seems more likely, they did not seek out the celebrated discoverer of the circulation of the blood. Unfortunately, all the record that we have of this visit is that passage in the work on the generation of animals in which Harvey describes the Bass Rock and its sea-birds, and dismisses as mere hearsay the stories of the generation of geese from the fruits of certain trees that had fallen into the sea. Even this treatise might not have come down to us but for Dr. Ent, to whom all later physiologists should return thanks; for Harvey in his age was discouraged and weary, but still working, and, as he said, "did I not find solace in my studies, and a balm for my spirit in the memory of my observations of former years, I should feel little desire for longer life." He had suffered irreparable loss when his house was pillaged and the fruits of many years of toil were taken from his museum, so that, as he said, "many observations, particularly on the generation of insects, have perished, with detriment, I venture to say, to the republic of letters."

\* This and other quotations are from Dr. Robert Willis's translation of the works published by the Sydenham Society, London, 1847.

There had been talk in Edinburgh of a College of Physicians for some years before the visit of King Charles I. and his Physician in Ordinary, and Sir Robert Philip suggests plausibly that Harvey was consulted on these proposals, as well as on others for the institution of a school of medicine as part of the "Tounis College," which afterwards became the University of world-wide fame. If in fact Harvey, who stood for all that was best in the spirit of the Royal College of Physicians of London in his day, and who was so much devoted to its interests, had no part in the proposals for the foundation of its younger brother of Edinburgh, yet we may be sure that he would have cordially welcomed its birth, which, however, did not take place till the year 1681, twenty-four years after Harvey's death and one hundred and sixty-three years after Henry VIII granted a charter to the London College. At least we know that his faithful disciple Sir Charles Scarborough, physician, mathematician, and anatomist, who accompanied the Duke of York to Scotland in 1679, had a good deal to do with the foundation of the College, and we can hardly doubt that he was thoroughly imbued with Harveian ideas.

Sir Walter Scott has painted vivid pictures of the conviviality of the lawyers of Edinburgh in his time. The leaders in medicine do not seem to have lagged behind them, for the Harveian Society, which grew out of the Aesculapian Club, was convivial as well as learned, and we suspect that its earlier name, or nickname, of "The Circulation Club" may have referred to the circulation of the bottle as well as of the blood. Sir Andrew Duncan, the "father" of the Royal College of Physicians of Edinburgh, records that Alexander Monro (*secundus*), the greatest of the three anatomists of that name, was a distinguished member, and that "without transgressing the bounds of the most strict sobriety, he afforded us demonstration of the exhilarating power of wine." Duncan himself was, as Sir Robert Philip tells us, promoted in 1815 to the degree of Doctor of Mirth, from which circumstance we may conclude that exhilaration on the occasion of Harveian banquets was not peculiar to Monro. The traditional day of meeting was April 12th, which is referred to as the birthday of Harvey, who, however, was born, like Prince Bismarck, on April 1st. Evidently the members of the Circulation Club were so conservative as to mark their opinion of the reform of the calendar by dining on the first of April, Old Style.

The Harveian Society of Edinburgh was established under that name in the year 1773, the same in which Dr. Samuel Johnson arrived in that city on his way to the Hebrides with the faithful Boswell, whose acquaintance was largely among lawyers, so that the great man was not introduced to many doctors. But he met the celebrated William Cullen, who seems to have humoured him dexterously; also Sir Alexander Dick, who was President of the Royal College of Physicians for seven years, and then retired of his own free will; as well as Dr. James Gregory, not long afterwards appointed to the chair of the Institutes of Medicine at the early age of 23. This versatile, witty, and quarrelsome man published an essay on "The theory of the moods of verbs" which would hardly have appealed to Harvey, who held with Galen that we should but agree about the things, and not dispute greatly about the words, for, as he says in another place, "We are too much in the habit, neglecting things, of worshipping specious names." Again, in a letter to Slegel of Hamburg he wrote: "You counsel well when you say, 'only make sure of the thing, call

it what you will.' " Harvey's clear and penetrating mind had little tolerance for verbal subtleties.

We may safely predict that the visitors at the Annual Meeting of the British Medical Association next July will find that hospitality and conviviality—within the limits of becoming mirth—are still practised on a generous scale in the venerable capital of Scotland, as they were on the occasions of former Annual Meetings there, when Alison, Christison, and Grainger Stewart successively adorned the presidential chair of the Association. Edinburgh, as is truly stated by the writer of another interesting article in this issue, powerfully stirs the imagination of all who know anything of its history, even if only through the pages of Scott and Stevenson. Like London, it had its Guild of Surgeons and Barbers, and, unlike London (which had to wait three centuries for its University), it had that celebrated child of the Reformation, the "Tounis College," founded in 1582, to which was added later a medical faculty that became in the eighteenth century of world-wide reputation. The union with England conferred great benefits on both countries, and, so far from prejudicing the University of Edinburgh, it increased its fame and its importance by attracting Englishmen, especially from the northern counties of the sister kingdom.

### LORD BALFOUR ON RESEARCH.

THE EARL OF BALFOUR has recently had occasion to deal with scientific research in two separate pronouncements, one relating particularly to medicine, the other in more general terms. Through his position as chairman of the Medical Research Council he has been afforded the opportunity of gaining a sympathetic insight into the aims and methods of research workers, while his philosophic temper and breadth of vision enable him to survey the wide domain of their activities with understanding. His views on research are therefore significant, and must command attention. Research in the common phrase may be taken to mean careful and diligent inquiry. In its scientific application it implies in addition the quest of something unknown. The serious research worker, having followed the made road to its termination, must pass beyond it into the undiscovered land where his field of action lies. The confirmation of points not fully known or insufficiently attested may for practical purposes be held to be included within the purview of research, but its true aim, its ultimate object, is "some new thing."

In his speech at the dinner of the Royal Society of Tropical Medicine and Hygiene, noticed in the JOURNAL last week (p. 1013), he put the case of a young medical graduate who goes out to a remote part of the Empire and finds himself forced by his sense of the situation to undertake research. Research conducted under these conditions must inevitably differ to some extent from work done at home. This is not to say that scientific work of high precision may not be carried through with conspicuous success in quite unfamiliar surroundings. The researches of Professor Barcroft and his party on the respiratory function of the blood at high elevations on the Andes are comparable in method and equivalent in accuracy to similar work at mean levels. But Barcroft's party had a travelling laboratory and lived in comfortable houses. The Everest expedition of 1924, on the other hand, could take no laboratory with them. They had no protection, save that of tents, from the icy mountain winds. Undeterred by the hardships which beset them they made unique

observations, but it was physically impossible for them to prosecute research of a sustained or elaborate kind. The case of Lord Balfour's medical graduate in some tropical outpost of British rule is, *mutatis mutandis*, akin to that of the Everest expedition. Though free from the distresses of life at high altitudes, he may suffer instead from the exhausting effects of hot humid air or endemic disease. Burdened with routine work, and, if he is a mobile officer in an undeveloped country, unable to take much scientific equipment about with him, he finds himself faced with medical problems, and sets himself to the task of their solution. His work in the circumstances described is a true research. He has passed beyond the made road of medical science. He is dealing with "some new thing." Even if the disease which is the subject of his investigation should prove in the end to be known elsewhere, his struggle has not been unavailing. He has established the fact of its presence in his area, he has made some contribution to its etiology and initiated measures which may ultimately lead to its extinction or effective control.

The second of Lord Balfour's two pronouncements, which relates to research in more general terms, forms an introduction to the Report of the Research Special Subcommittee of the Imperial Conference set up to consider the question of research from the economic standpoint. The subcommittee suggested to the Conference the need for the fullest practical co-operation between the organizations within the Empire respectively responsible for agricultural, fisheries, forestry, medical, and industrial research, the quick and orderly exchange of results, and the fullest possible discussion of problems of common interest. The subcommittee did not consider that all imperial research organization should necessarily be centred in Great Britain: an organization for veterinary science, for example, might conceivably be set up in South Africa. Gaps in knowledge might usefully be discussed at the conferences which they propose. For medical purposes good co-ordination would be effected if each part of the Empire were permitted to nominate a representative to the quarterly standing conferences of the Research Council.

In presenting the report of the subcommittee Lord Balfour recalled, among other things, that neither money nor organization can increase the supply of original scientific genius. This is a pertinent reservation which is sometimes too little remembered. Money and organization can provide well furnished premises, suitable to be places of research, but they cannot ensure the provision of the mental equipment necessary for turning them to the highest uses. The most lavishly fitted laboratory, uninspired by some creative mind, will never produce first-grade work. The worker is the essential factor, not the workplace. Epoch-making researches of gifted men have before now been carried out with modest or meagre laboratory equipment. Pasteur's best work was done under such conditions, for the Pasteur Institute came as a recognition of his greatness, not as a means to it. But, given a creative mind to animate and direct, a well equipped laboratory or institute for the promotion of research is obviously great gain.

Lord Balfour, while commending the principle underlying the subcommittee's suggestions for the co-ordination of research, expresses himself as averse to any form of imperial control with this object. Despite his reservation as to the supply of genius he was hopeful that much may be accomplished in the way of improvement "if we are not too ambitious."

There are at this moment in different parts of the Empire a large and increasing number of institutions devoted to research. They provide a basis to work on. Let easy exchange be cultivated between them, and full co-operation will follow. Intellectual waste will thus be diminished, and investigators in the same scientific field, though far separated in space, will be able to work together as partners.

In these two pronouncements Lord Balfour glances at research from two slightly different angles. In one he is concerned with the medical pioneer working under difficulties, in the other with the economic research worker in an organized institute who has ample resources to his hand. In both cases, however, he equally lays stress on the need for exchange of ideas and results, in order to prevent overlapping and save time and labour. It would appear to be not less needful that the results of work in the institutes and scientific departments of the various Governments of the Empire, both in England and overseas, should, when completed, be published in such a manner as to be readily accessible, not only to Government departments, but also to scientific workers in general. The Medical Research Council in this particular has set a good example. The reports of its observers are usually published as pamphlets of handy size, and at a price which is doubtless as favourable to purchasers as circumstances permit. Reports buried in reports of local governments escape the notice of many who would gladly profit by their perusal, and the medical and scientific press, desiring to do the best for its readers, cannot reproduce them verbatim for the information of the few, to the exclusion of topics of more general interest. A scheme of authentic publication, like that of the Medical Research Council, would, if adopted by Governments and their departments, greatly help the scientific worker. It would bring within his reach authoritative information on his own subject in a convenient form, and, amid the mass of material in the guise of science which pours at the present time from the printing presses of every civilized country the whole world over, it would give him, if not always "some new thing," at least some sure thing to guide his further progress. Such a scheme, as an adaptation of the principles commended by Lord Balfour, would advance the cause of true research.

#### CENTENARY OF LAËNNEC.

It is a hundred years since the death of the illustrious Laënnec, and it is also exactly a hundred years since the second edition of his masterly work the *Traité d'Auscultation* was published. The Académie de Médecine has taken the initiative in celebrating this double anniversary by a series of séances on December 13th, 14th, and 15th. On the afternoon of Monday, December 13th, receptions will be given at the Académie de Médecine and the Hôtel de Ville; in the evening there will be another at the Sorbonne in the presence of the President of the Republic; addresses will then be given by the Rector, Professor Ménétrier (on the discovery of auscultation), by Professor d'Arsonval (on Laënnec and the Collège de France), by Professor Roger (on Laënnec and the Faculté de Médecine), and by Professor Léon Bernard (on tuberculosis since Laënnec); after these, addresses from the foreign delegates. On Tuesday, December 14th, there will be in the morning a visit to the Musée Carnavalet; at 3 p.m. a sitting at the Académie de Médecine and addresses by Professor Bar, by Professor Miraillé (the medical beginnings of Laënnec), by Professor Letulle (Laënnec as a pathologist), by Professor Sergent (Laënnec as a clinician), and by Professor

Achard (the role of Laënnec in the evolution of medicine). There will also be an exhibition of souvenirs. On Wednesday, December 15th, there will be a reception at the Hôpital Laënnec and an address by Dr. Rist, followed by a visit to the Hôpital Necker and the Hôpital de la Charité. In the afternoon, during a visit to the Institut Pasteur, Dr. Calmette will give an address on the prevention of tuberculosis since the days of Laënnec. The fêtes will close with a banquet the same evening at the Palais d'Orsay. All who desire to join in these interesting ceremonies should communicate with the Secretary-General, Dr. Roussy, 21, Rue de l'École de Médecine, Paris, 6. We understand that the Royal College of Physicians will be represented by Sir John Broadbent, and that the Royal Society of Medicine has nominated Sir StClair Thomson as its delegate.

#### GENERAL MEDICAL COUNCIL.

THE winter session of the General Medical Council was unusually brief, lasting only four days, and the disciplinary cases were few in number and raised no novel points of professional conduct. Not a single case was concerned with misleading certification or with "covering," and the one case in which the complaint related to advertising had to do with an Indian practitioner advertising in a Burmese newspaper. Three of the cases related to charges of drunkenness. One of these was dismissed with a caution, and in the other two judgement was postponed for twelve months to give the respondents time to consider their position. In another case the charge was that of professional relationship during adultery. The usual defence in such charges is that professional relationship had ceased before adultery began, but in this case the defence was that the adultery preceded such professional relationship as existed. The Council dismissed the case. The inquiry which occupied the longest time concerned a complaint against a practitioner for unprofessional conduct towards a female patient, the patient appearing as complainant. The solicitor for the complainant asked that the case might be heard *in camera*, and the solicitor for the respondent having no objection, the Council agreed, and strangers, including the press, withdrew. The result of the case was the erasure of the name from the *Medical Register*. The remaining business of the Council was disposed of in half an hour; it consisted of reports of committees which dealt merely with routine matters, but the Council considered for a long time *in camera* the question of the restoration of certain names to the *Register*. The President's introductory address was printed in full in last week's SUPPLEMENT (p. 225), and our report of the session is continued this week.

#### THE TERMINOLOGY OF VISION.

WRITERS of scientific treatises have constantly to beware of the danger of their readers misunderstanding the technical terms they use. In the absence of a technical dictionary the reader may tuck away the phrase or word in his mind for future reference, or may presume it to mean something different or less exact. Moreover, scientific terminology is constantly widening. A technical dictionary is quickly out of date, not merely because new terms are invented, but because old terms are dropped or are given a more restricted meaning. Take such a common expression as the fundamental unit in photometry—"candle-power." When we discuss the brightness of a lamp we speak of it as of high or of low candle-power. Hitherto this has been a general expression for brightness, but photometrists have lately introduced the term "luminous intensity" for use when no actual measure is involved, and have reserved the term "candle-power" strictly for intensity as measured by the international candle, a unit

maintained by a group of incandescent filament lamps at the National Physical Laboratory in this country and the corresponding institutions in Paris and Washington. Perhaps the wise author will include a glossary in his work so that there will be no misinterpretation. The Illumination Research Committee of the Department of Scientific and Industrial Research has hit upon an even better method; it publishes from time to time a series of technical essays on particular pieces of work, mostly relating to specific problems in industrial illumination, such as the light distribution of certain reflectors, and the absorption of light by window glass, and it has taken the precaution to devote the first of these essays simply to terminology in order that those who read what comes afterwards may have a clear apprehension of the terms and symbols. This essay, published in a pamphlet with the title *The Terminology of Illumination and Vision*,<sup>1</sup> adopts, not the alphabetical order of the dictionary, which is the crudest of classifications, however convenient, but the natural order of the subject as a student would approach it, proceeding from the simple to the complex, from the general to the particular, and from the regular to the anomalous. Certainly it is helpful to the memory to come upon a certain term with its definition, not isolated among words with which it has nothing in common except that their initial letters are the same, but branching out from other terms which up to a point have the same meaning. Even the casual student in that way begins to appreciate that the terms used in ophthalmology, for example, are not erratically chosen, but hang together and are themselves a science. Take, for example, the disturbance of muscle balance in the eye, which is spoken of as "heterophoria." If the deviation is a convergence we have "esophoria," if a divergence "exophoria," if vertical "hyperphoria." In a few pages the Illumination Research Committee manages to bring into a clear narrative practically all the more common terms used in photometry and illumination on the one hand and physiological optics on the other. The latter section begins with a simple description of the structure of the eye, its dioptric mechanism, whereby images are brought to focus on the retina, the adjustment of this mechanism by accommodation, and its anomalies, which involve such terms as anisometropia, hypermetropia, and myopia. The co-ordination of the movement of the eyes brings in another set of terms, and a simple explanation is given of what is meant by the visual field and by binocular and stereoscopic vision; then come the three visual sensations—the light, the form, and the colour sensation—and the tests for each. The same plan is followed with the terms in photometry and illumination, which are even more formidable than those in ophthalmology, and are fully to be apprehended only by the mathematician.

#### GENERAL PARALYSIS IN PRIMITIVE RACES.

PROFESSOR FELIX PLAUT of Munich has recently given an interesting account<sup>2</sup> of a tour undertaken in company with the late Professor Emil Kraepelin to determine the prevalence of general paralysis among negroes and Indians in the United States, negroes in Cuba, and Indians in Mexico. During the eighty clear days which they had at their disposal the writers investigated North American negroes in the St. Elizabeth Hospital at Washington, Cuban negroes in the Mazorra Institute at Havana, North American Indians in the Asylums for the Insane at Canton, South Dakota, and Mexican Indians in the general asylum in Mexico City. Their investigations led them to conclude that during the last ten to fifteen years syphilis has been

twice as frequent among the negro men and three times as frequent among negro women as in the corresponding sexes of the white race. Certain differences in the course of syphilis were noted among North American negroes, such as the rarity of extragenital chancres, peculiarities in the form and extent of the secondary eruptions, and appearances of gummata on parts of the body seldom affected in the white race, and the fact that the osseous system is involved twice as frequently as in whites. The inquiry showed, however, that the negroes in North America were as susceptible to general paralysis as the whites, and that the incidence of cerebral syphilis among negroes in asylums was relatively high. Whereas in 1922 the incidence of general paralysis among the negroes showed only a slight excess over that among the whites (11.6 per cent. as compared with 8.5 per cent.), cerebral syphilis was four times as frequent among the negroes as among the whites. General paralysis was rare among the negroes of Cuba, who, though not quite so often infected with syphilis as the North American negroes, are sufficiently often attacked to render a higher incidence of general paralysis probable unless some protective influences were at work. The nature of these influences was not ascertained. General paralysis is also decidedly rare among the North American Indians, in spite of the relatively high incidence of syphilis. Predominance of skin and bone syphilis cannot account for this, as the disease appears to be of a milder type than in the neighbouring white races. Syphilis was found to be very prevalent among Indians in Mexico City, and the frequency of general paralysis among them did not appear to differ essentially from that found in the asylums of North America and Europe.

#### TWO MEALS A DAY.

ANDREW BOORDE, who was born in or about 1490 at Cuckfield in Sussex, began life as a monk and was afterwards nominated suffragan Bishop of Chichester, although he never seems to have discharged any episcopal duties. He finally obtained dispensation from his orders, and became a physician. Partly to improve his knowledge and partly to find out what was thought of Henry VIII, he travelled over many parts of Europe, and, like a sixteenth century Flexner, visited and inspected many universities. Some have supposed him to be a Scot because he studied at Glasgow; but he, in fact, had a very poor opinion of Scotsmen. In addition to a sort of guide-book to Europe he wrote several medical books, including one entitled *Dietary*, in which he gave much shrewd advice. Of a man's ordinary diet he said: "Two meales a day is suffeycent for a rest man; and a laborer may cate three tymes a day; and he that doth eate after lyveth a bestly lyfe." Mr. Salzman, who quotes this in his *English Life in the Middle Ages* (London: Humphrey Milford), says that at the time when Boorde wrote "the two universal meals were dinner, taken about 10 or 11 in the morning, and supper, for which the usual hour was 4 o'clock. . . . Mediaeval cookery was more elaborate than is often realized. A great variety of soups, stews, pasties, fritters, jellies, and so forth were in common use, and the recipes that have survived from the fifteenth century show that many dishes were of very elaborate composition, most containing quantities of spices." As an instance of an elaborate recipe Mr. Salzman takes that for "leche lumbard," which was something in the nature of a saveloy or German sausage: "Take pork and pound it in a mortar with eggs; add sugar, salt, raisins, currants, minced dates, powdered pepper, and cloves, put it in a bladder and boil it; then cut it in slices." This was served with a sauce made of raisins, red wine, almond-milk coloured with saffron, pepper, cloves, cinnamon, and ginger. If our forefathers of the sixteenth century only had two meals a day,

<sup>2</sup> *Paralysestudien bei Negern und Indianern: Ein Beitrag zur vergleichenden Psychiatrie.* Von Dr. Felix Plaut. Mit einem Geleitwort von Prof. Emil Kraepelin. Berlin: Julius Springer. 1925. (Sup. roy. 8vo, pp. 52; 15 figures.)

each would seem to have been copious whenever the house could afford it. Mr. Salzman quotes some rhyming instructions, one of which is:

"Defyle not thy lips with eating much, as a pigge eating draffe;  
Eate softly and drinke mannerly, take heed you do not quaffe."

It would seem, however, that our forefathers had some difficulty in providing meals containing much meat during the winter season. The system of saving fodder from the summer and late autumn was not efficient, and cattle had to be killed and cured in the autumn—at any rate, that was the case a century earlier. The dearth of fresh meat accounts for the obligation there was on the lord of the manor to keep a capacious pigeon cote. Probably he ate most of the pigeons himself, but doubtless the tenants took toll. If we come to the next century we find a considerable number of entries in Pepys's Diary of what he ate for dinner, which seems to have been a movable feast any time between noon and two o'clock; the latter hour probably was exceptional, and due to the pressure of his work and the talkative habits of committees, which would sometimes sit much longer than he thought at all necessary, but without getting very much work done. This fault is not altogether unknown at the present day.

#### RECENT RESEARCH IN FOOT-AND-MOUTH DISEASE.

THE epizootic of foot-and-mouth disease which has been present in this country for the past few years appears to have reached its zenith in 1923, when over a quarter of a million animals were slaughtered, at a direct cost to the country of 2½ million sterling in compensation alone. During 1925, according to a recent report of the Ministry of Agriculture, only twenty thousand animals were slaughtered, and the compensation amounted to just over a quarter of a million sterling. Research is still continuing both here and abroad. At home there is little advance in the state of affairs previously reported in these columns. Investigations, however, have been conducted into the plurality of viruses, and the existence of two separate types (corresponding to the A and O strains of Carré and Vallée) has been confirmed in this country. Stockman and Minett<sup>1</sup> have investigated seventeen strains from various outbreaks in Great Britain, and find that sixteen of these were of the O type and only one of the A type. (The terms O and A were originally given by Carré and Vallée to strains collected in the Oise (O) and in Germany (A).) It has previously been suggested<sup>2</sup> that man might be relatively insusceptible to one of these types, and if this hypothesis can be confirmed it would serve to explain the comparatively small number of human infections in Britain. The O type seems to produce a much milder form of disease in cattle than the A type—the incubation period is longer, the lesions are less extensive, and there may even be no clinical signs of the disease. It is significant that many of the human epidemics have occurred in Germany, and it is suggested that these may be A type infections. Most of the cases recorded from this country have been very mild, compared with the sometimes fatal Continental cases, and would probably be O type infections. It has previously been suggested that these types should be referred to as aphthous and paraphthous fever. Recently, however, Waldmann and Trautwein<sup>3</sup> have reported the existence of a third type in Germany, and the suggested nomenclature would seem to be insufficient without the assistance of the alphabet in a manner analogous to the typhoid fevers in man. Meanwhile the American commission on this disease has visited the Continent, and has issued an interim report.<sup>4</sup> In horses, especially in the United States, there exists a disease called vesicular stomatitis, which clinically resembles foot-and-

mouth disease very closely. The commission found that injections of material from vesicles of this disease into guinea-pigs produced lesions almost identical with those of foot-and-mouth disease in these animals; the viruses could be distinguished by cross-immunity tests, however. The commission found also that injections of this virus into cattle produced what appeared to be foot-and-mouth disease, but there was less tendency to produce vesicles on the feet than in the classical disease, and the one virus gave no immunity against the other. Pigs appear to be equally susceptible to either virus, and the lesions, both on the mouth and the feet, are indistinguishable the one from the other. Here again there is no cross-immunity. But neither do the A and O viruses of foot-and-mouth disease give any cross-immunity. The horse shows a considerable resistance to true foot-and-mouth disease (the American commission was quite unable to infect this animal experimentally), but it is very susceptible to vesicular stomatitis, lesions developing not only on the mouth but sometimes also on the feet. This appears to be the greatest difference between the two diseases, and accordingly there seems no valid reason why vesicular stomatitis should not be considered a variety of foot-and-mouth disease. The present position seems to indicate that foot-and-mouth disease, like distemper in dogs and coryza in man, is not a single disease but a whole group of diseases with somewhat similar clinical symptoms, but producing no immunity against each other—which promises very considerably to complicate the bacteriological fight against it.

#### ILLUMINATION IN PRINTING ROOMS.

THE Departmental Committee on Factory Lighting appointed by the Home Office in 1913, in its third report, after classifying a variety of processes as "fine" and "very fine," urged the importance of obtaining more precise knowledge of the conditions of illumination desirable on physiological and psychological grounds for such work. This was one of the problems submitted to the Illumination Research Committee appointed by the Department of Scientific and Industrial Research to study illumination on general lines, and the committee decided to select hand composing in letterpress printing as the first example of fine work to be studied. The collaboration of the Medical Research Council was invited, and it appointed Mr. H. C. Weston and Mr. E. K. Taylor, of the National Physical Laboratory, to assist in the inquiry, and the Joint Industrial Council for the Printing and Allied Trades nominated two representatives to the special subcommittee appointed to supervise the investigation. The observations were carried out at the printing works of Messrs. Kelly's Directories. The most striking conclusion is that all printing offices would seem to be insufficiently lighted. It appears that some of them have less than 2 foot-candles; with this insufficient illumination nearly a quarter of the possible output is lost, the number of mistakes is more than doubled, and the fatigue experienced by the compositors materially increased. Even when the illumination is as much as 7 foot-candles—a value which is thought to be higher than the present general practice—over 10 per cent. of the possible output is lost, and there is a high percentage of errors. The committee concludes that there is an optimum value of illumination for hand composing, and that it is of the order of 20 foot-candles. If the installation is well planned so as to secure approximate uniformity of illumination over the whole area of work, it may be expected that the daylight rate of output will be maintained, at any rate for the short periods for which an artificial light is required in ordinary printing offices during the year. When work has to be done continuously by artificial light, as in newspaper offices, the provision of

## THE GENEVA OPIUM CONVENTION.

higher values of illumination is essential if the efficiency of a night shift is to approach that of a day shift. If work is done in artificial light only for a few hours a day, no evidence was found that any undue ocular fatigue is likely to result, providing the illumination is uniform and of the order of at least 10 foot-candles.

## THE GENEVA OPIUM CONVENTION.

THE Geneva Opium Convention of February, 1925, from which such beneficial results were anticipated by those who framed it, has not yet come into force. It cannot do so until it has been ratified by ten of the signatory Powers, including seven of the principal States in respect of which the Central Board to supervise its operation is to be formed. The Secretary of State for Foreign Affairs recently made in the House of Commons the unsatisfactory announcement that only the British Empire (excluding Canada and the Irish Free State), the Sudan, and Portugal had deposited ratifications. It was claimed by M. Zahle, the president of the Second Geneva Conference, that the convention signed in February, 1925, had "provided the mechanism for its own realization," and that it "had greatly initiated a movement which will accelerate from day to day and from month to month," and that it "had greatly strengthened the Hague Convention of thirteen years ago." This sanguine anticipation has not so far been realized. Reports of illicit traffic in opium, morphine, and cocaine abound. The immense excess of production over any conceivable legitimate use is notorious. The extinction of the export trade in Indian opium, mostly used for smoking, will not be completed for ten years. Critics of the Geneva conferences freely declared that "the agreement of the First Conference represents no progress worth discussing, and the new drugs convention adopted by the Second Congress is a thing of printed paper with the odds heavily against it ever being anything else." It is perhaps some consolation to learn from Sir Austen Chamberlain's recent reply that "The Hague Convention of 1912 continues in operation as between the States parties to it." It will be remembered that the American delegation at Geneva regarded the convention of 1925 as in some respects a less satisfactory instrument than that of 1912, and complained that some of the obligations envisaged by the latter had not been carried out. More recently the Italian representative at the League of Nations declared that the unrattified convention of 1925 was in some respects a step backwards from the Hague Convention of 1912. If the earlier convention was lacking in the provision of adequate machinery to attain its objects, it was largely because the British Government instructed its delegates to refuse to discuss "the advisability of an international commission to be entrusted with the carrying out of any international agreement concluded." The present position is highly unsatisfactory, and can only be regarded with equanimity by those who profit by the traffic in dangerous drugs, or who are loath to restrict their employment exclusively to medical and legitimate uses.

## LOCUSTS IN MEXICO.

GREAT BRITAIN, fortunately, is not infested by locusts, but this plague, which we are accustomed to associate with the name of Moses, is by no means uncommon in many countries at the present day; and those who have witnessed smiling orchards and green fields stripped of every vestige of their vegetation in a single night, and have seen the devastating hordes advancing in solid masses to the limits of the horizon, will realize the importance of investigations which throw light on the life-history and habits of these pests, and indicate the direction to be taken in formulating measures for their destruction. We welcome, therefore, a valuable contribution to our knowledge of the subject that

comes from Mexico in the form of a report by a scientific committee appointed to investigate a plague of locusts which invaded the State of Vera Cruz in 1923 and continued in successive waves in 1924. Oddly enough, the committee was appointed, not because of the destruction caused to the agricultural interests of the State, but on account of complaints made to the health authorities of the pollution of water supplies by the dead bodies of the locusts. The committee carried out its investigations in the autumn of 1924, and the report now published bears the names of its three members, Dr. Carlos Hoffmann, professor of zoology in the National University, Dr. Dampf, professor of entomology in the National School of Agriculture, and Señor Gerardo Varela, assistant in the bacteriological department of the Mexican Institute of Hygiene. Their report contains five chapters. The first, by Professor Hoffmann, gives the history and progress of the plague and the situation at the beginning of November, 1924, when the report was submitted. The second chapter, by Dr. Dampf, is a contribution to the morphology and bionomics of the *Schistocerca paranensis* Burm., the locust which caused the plague. The third chapter, by all three members of the committee, contains observations on the parasites that are found on and attack the locusts; the fourth chapter, by Dr. Dampf and Señor Varela, is a study of the carcasses of the locusts; and the final chapter, by Professor Hoffmann and Señor Varela, investigates the nature of the pollution of water supplies by the dead bodies and their influence in spreading disease. The report is extremely well and clearly written. It is illustrated by excellent photographic reproductions and drawings, and gives a short bibliography at the end of each chapter. It embodies a scientific investigation that is worthy of study by all who are interested in the bionomics of locusts or in the prevention of the appalling devastation caused by them from time to time in so many quarters of the globe.

## THE ASSOCIATION IN 1926.

THE middle pages of the SUPPLEMENT this week are addressed to medical practitioners who are not already members of the British Medical Association, and in particular to those who have lately joined the ranks of the profession. A brief account is given of the chief aims of the Association, its work and organization, and of the privileges and responsibilities of membership. The remarkable growth of the Association in recent times is brought out graphically in a chart showing the number of members year by year since 1876. In the past twelve months there has been a further gain of nearly 2,000, the total on November 25th, 1926, being 32,330. The numerical strength of a professional body is not, of course, the only test of its vitality, but a net increase of more than 12,000 since the war speaks for itself. During the same period the number of names in the *Medical Register* has increased by about 7,000.

SIR THOMAS LEGGE, M.D., who has been H.M. Medical Inspector of Factories since 1898, states in a letter to the *Times* that he has resigned that appointment because he cannot recede from the position he took up at Geneva in 1921, when, as one of the delegates of the British Government, he voted for the draft convention prohibiting the use of white lead for internal painting of buildings. As recorded in our Parliamentary column last week (p. 1025), the Lead Paint (Protection against Poisoning) Bill reached its final stage in Parliament on November 18th. In it the Government adopted the policy of action by regulations for the prevention of lead poisoning among house painters, instead of the prohibition of lead painting for interiors recommended by the International Labour Conference at Geneva five years ago.

# NINETY-FIFTH ANNUAL MEETING of the British Medical Association, EDINBURGH, 1927.

Edinburgh Castle.

THE ninety-fifth Annual Meeting of the British Medical Association will be held in Edinburgh next summer under the presidency of Sir Robert Philip, M.D., LL.D., honorary physician to the King in Scotland, who will deliver his address to the Association on the evening of Tuesday, July 19th. The sectional meetings for scientific and clinical work will be held, as usual, on the three following days, the morning sessions being given up to discussions and the reading of papers, and the afternoons to demonstrations. The Annual Representative Meeting, for the transaction of medico-political business, will begin on the previous Friday, July 15th. The provisional programme for the work of the twenty-one Scientific Sections is being drawn up by an Arrangements Committee, consisting partly of Edinburgh representatives and partly of members appointed by the Council of the Association. The names of the Presidents of Sections are given in a Current Note published in this week's SUPPLEMENT; the full list of officers, together with other details of the arrangements for the Annual Meeting, will appear in later issues. On the last day of the meeting (Saturday, July 23rd) there will be excursions to places of interest in the neighbourhood. The Association last met in Edinburgh in 1898. We publish below the first of a series of articles on the past history and present activities of the Scottish metropolis and its world-renowned medical institutions.

## OLD EDINBURGH AND THE BEGINNING OF THE EDINBURGH MEDICAL SCHOOL.

EDINBURGH is a town that powerfully stirs the imagination, both by its natural beauties and by reason of the tradition and romance which cluster round its streets and buildings.

The Castle Rock and the surrounding hills have been the seat of human habitation and warfare since prehistoric times. Cramond and Musselburgh, on the city boundaries, show remains of occupation as Roman military posts, and the wall of Agricola, between the Firths of Forth and Clyde, which formed the northern boundary of the Roman Empire, ended some eighteen miles west of Edinburgh. In the Castle to-day are still to be found buildings to remind the visitor of Margaret, the saintly queen of Malcolm Canmore, who did much to civilize and Christianize Scotland; of David I, that "sair saint for the Croon," who founded the beautiful abbeys of Jedburgh, Kelso, Melrose, Dryburgh, Newbattle, and Holyrood, and who introduced the feudal system into Scotland; and of the troubled and romantic times of the unfortunate Mary Queen of Scots. From the Castle the historic mile leads down the High Street, past St. Giles Cathedral and John Knox's house and the old dwellings of the Earl of Moray, Lady Stair, the Earl of Huntly, and others of the ancient Scottish nobility, to Holyrood, with its palace and ruined abbey, again associated with the fortunes of Mary Queen of Scots. On the north of this old town lie Princes Street Gardens, once occupied by the Nor' Loch, which protected the city on this side, while half a mile or

so from the High Street, on the south, can still be found remnants of the old city wall, which formed the buttress against "our auld inemys of England." Immediately within

the precincts of the old wall stood in the fifteenth and sixteenth centuries several religious houses, whose names are still preserved in Blackfriars Wynd, Greyfriars Churchyard, and the Pleasance, where the convent of Saint Mary of Placentia formerly stood. On the site now occupied by the University buildings, about one mile from Holyrood, stood Kirk o' Field, the house in which the unhappy Darnley was blown up in 1567 during the progress of a masque at the Palace. Among the other buildings still extant and connected with celebrated names of bygone days are Heriot's Hospital, built with funds supplied by "Jingling Geordie," the Treasurer of James I of England; Merchiston Castle, where John Napier worked out his logarithms; Lauriston Castle, the home of John Law, the floater of the Mississippi scheme; and the houses of Sir Walter Scott, Lister, John Brown, and many others who have contributed to the fame of the scientific and literary life in Edinburgh.

FIG. 1.—Convening House of Barber-Surgeons in Dickson's Close (still standing).

Edinburgh is situated on high ground overlooking the Firth of Forth, with Leith, now absorbed in the city, but until recently a separate burgh, as its seaport. Some nine miles to the north-west, the Firth of Forth is crossed by the Forth Bridge, near which lies Rosyth Dockyard and the naval anchorage, a place of great activity during the

FIG. 2.—The 1697 Surgeons Hall, with old City Wall in background. (Hall still standing with part of wall.)

war. In the Firth lie the islands of Inchcolm, with an old abbey and the monastic cell of one of the early Christian missionaries to Scotland, and further to the east the Bass Rock, with an ancient fortress. To the south of the city the rich agricultural district of the Lothians stretches to the Moorfoot and Lammermoor Hills. In the middle of the plain stands up Traprain Law, a steep rounded hill once crowned by a primitive hill-fort, in which some years ago was unearthed a great hoard of silver vessels, the plunder of Roman towns in Gaul. South of the hills lies the fair valley of the Tweed, celebrated in border minstrelsy and legend. It is a commentary on the change wrought by time that at the present day one can lunch at Edinburgh and comfortably take tea at Otterburn, where, in 1388, took place between the Scots and English what Froissart calls "the hardest and most obstinate battle that was ever fought," and where the dying Douglas said:

"But I have dreamt a dreary dream,  
Beyond the Isle of Skye,  
I saw a dead man win a fight,  
And I think that man was I."

The road along Tweedside by Peebles and the abbeys of Melrose, Dryburgh, and Kelso, ruined during the incursions of Somerset in the time of Henry VIII, is one of the most beautiful in Scotland, and an easy afternoon's motor run from Edinburgh.

The union of the crowns under James VI of Scotland and I of England in 1603 was a great blessing to both countries by putting a stop to the constant warfare on the border, and since that date the peaceful penetration to London has been the aim of all ambitious Scots. In mediaeval times Scotland was a poor country, although intercourse and alliance with France brought to the northern country many intellectual advantages which have left traces on Scottish architecture, habits, and language. The desire for education was satisfied by many monastic settlements, and Haddington, some seventeen miles east of Edinburgh, was the seat of a school and abbey church known far and wide as "The Lamp of Lothian." Here William Dunbar, John Knox, George Buchanan, and Sir David Lindsay were educated. St. Andrews, in Fife-shire, had schools which were noted in the twelfth century, and a university founded in 1411. The University of Edinburgh, a child of the Reformation, was founded as the "Tounis College" by the town council in 1582. In regard to medicine, in Scotland as in other countries from early times churchmen, who had obtained a knowledge of medicine during travels abroad, were found in the religious houses. Such a one was Michael Scot in the twelfth century, who returned to Scotland in his declining years to be buried in Melrose Abbey,

"A Wizard of such dreaded fame,  
That when in Salamanka's cave  
Him listed his magic wand to wave,  
The bells would ring in Notre Dame!"

There also existed in the highlands a peculiar type of hereditary doctor, especially in the family of Beaton or Macbeth, attached to some of the great families, and handing down their medical traditions from father to son through many generations. In the towns, and notably in Edinburgh, there were guilds of barber-surgeons, as of other trades, and in the fifteenth century the brethren of the Guild of Surgeons and Barbers maintained an altar, where daily services were held, in the Kirk of St. Giles, under the patronage of St. Mungo. In the year 1505 this guild received a charter of incorporation from the town council, confirmed the next year by King James IV. Among the conditions stipulated in this charter was a provision that every man before he became a freeman and master of the craft should submit to an examination in the following points, "that he know anatomea, nature and complexioun of every member In manis bodie And in lykewayes he know all the vayneis of the samyn thatt he may mak flewbothomea in dew tyme And als that he know in quihilk member the signe hes domination for the time." Further, no master was to take an apprentice to practise the craft of surgery unless he could both write and read—a sign of unusual erudition in those days. A noteworthy concession by the town council, as indicating the beginning of public teaching, is the grant to the guild "that we may have anis in the yeir ane condampnit man efter he be deid to mak anatomea of quhairthrow we may haif experience Ilk ane to instruct utheris." Doubtless the yearly anatomical demonstration was carried out in the same manner as that by which Mondino had lectured at Bologna two centuries earlier, and seeing there was much intercourse in the sixteenth century between Scotland and the Continent, probably Mondino's little textbook was used, or that of his contemporary, Henri de Mondeville of Paris and Montpellier. Although public dissections had been carried out in most of the Continental universities in the fourteenth and fifteenth centuries (Venice from 1308), this was the first enactment on the subject in Britain, preceding even the law of Henry VIII in 1540, by which four bodies of executed criminals were granted to the barber-surgeons of London. During the next half-century Edinburgh suffered several disasters, commencing with the battle of Flodden, and continued by the destruction wrought in the English invasions under Somerset. In 1558, indeed, the Incorporation of Surgeons supplied twenty-five of their number, including apprentices, to a force of Scots and French operating against England.

While minor surgery was left in the hands of the barbers and their apprentices, there were in the sixteenth century at Edinburgh several distinguished surgeons who had been trained abroad, especially in the French wars. Among these were Anthony Brisset, who treated Queen Mary of Guise (1542), Gilbert Skene, who published at Edinburgh a treatise on the plague (1568), John Chisholm,

who operated on the Regent Earl of Morton for strangulated hernia (1572), and Gilbert Primrose, chirurgion to James VI and Deacon of the Craft of Chirurgeons (1583), under whom this guild was granted pre-eminence among the trade guilds of Edinburgh. An apprentice of the last in 1587 was John Naysmyth, later chief surgeon to the Scots Guards of the King of France. The social status and professional skill of these sixteenth century master surgeons of Edinburgh, relative to other callings and to the general knowledge of the time, was at least as high as that of surgeons at the present day. Several of them possessed considerable heritable property in the city or estates in its vicinity. Their number was not large, as may be gathered from the fact that in the year 1648 they totalled only ten.

While the demonstration of anatomy by the barber-surgeons on the bodies of executed criminals probably continued year by year, a definite teacher of anatomy is not mentioned until 1645. The master surgeons had presumably given yearly demonstrations in rotation conformably to the words of the original charter "ilk ane to instruct utheris." In this year James Borthwick, a burges of Edinburgh, having duly passed his examination, was admitted as a master surgeon for the special purpose of "desceting of anatomie for the farder instruction of prentissis and servandis." Borthwick had served abroad through the Thirty Years War and been chirurgion-general to the Auxiliary Scots Army in England during the civil war. It had been the custom till now to hold the meetings of the craft in the house of the deacon for the time being, and one can imagine that the anatomical instruction must have caused some awkwardness in his domestic arrangements. In 1647 David Kennedy and James Borthwick reported that they had taken as a place of meeting "three rowmes of ane tenement of land in Diksone Close, for payment of fourtie poundis zeirlic." This tenement in a derelict condition still stands near the end of Dickson's Close. In 1669 the Incorporation of Surgeons and Barbers had become so important that it was decided to build a "conveening house" on a piece of ground in the south-east angle of the city wall, presented to them by the town council in 1656. Each member subscribed £100 for that purpose. The grant of further sources of anatomical material by the town council made it possible by Michaelmas, 1697, to build, repair, and have in readiness an anatomical theatre for public dissections. From December, 1697, therefore, the teaching of anatomy in Edinburgh became systematic. Archibald Pitcairne, Alexander Monteth, and others gave combined anatomical demonstrations, and we find Pitcairne, who had for two years been a professor of medicine in Leyden, writing in 1694 to a friend in London that he proposed "to make better improvements in anatomy than have been made in Leyden these thirty years." The Tounis College for the study of the humanities, established by the town council in 1582, had not yet made any provisions for medical teaching. In 1676, however, the town council appointed James Sutherland professor of botany, and three professors of medicine—Dr. A. Pitcairne, Sir Robert Sibbald, and Dr. James Halket—were added to the College in 1685. These appointments appear to have been mainly titular, and there is no evidence that any of the three gave a systematic course in medicine.

The general practitioner of the seventeenth century in

Scotland, as in England, was a surgeon apothecary, professing to heal wounds and cure diseases, making and selling drugs, operating with instruments often made by the local blacksmith and much inferior to the fine steel instruments of the French surgeons. He bound himself for an apprenticeship of three years, and received instruction from the master whom he helped in practice, not being permitted to attend any lectures for the first two years; and probably the majority, unless they lived in one of the towns, never attended any lectures, and stood a very perfunctory examination before they were licensed to practise. In seventeenth century Edinburgh there were, however, several skilled physicians who had obtained diplomas at French or Dutch universities. Among these were Sir Robert Sibbald, Sir Andrew Balfour, Sir Archibald Stevenson, Dr. Archibald Pitcairne, and Sir Thomas Burnet, the brother of Bishop Gilbert Burnet, celebrated for his share in the revolt against James II, and for bringing over William of Orange. This group of men decided on the foundation of medical teaching on a better basis than hitherto at Edinburgh. Among their activities

was the founding of a College of Physicians, which finally obtained a charter from Charles II in 1681. By this College an Edinburgh Pharmacopoeia was issued in 1699. This compares favourably, in the relative absence of disgusting remedies, with the current London edition of the *Pharmacopoeia*, which had been first issued by the London College in 1618. Another of their resolves was to found a complete medical school in Edinburgh. This began as a development of the anatomical teaching already mentioned; in 1702 a course of anatomical demonstrations was carried out by several members of the Incorporation of Surgeons. This anatomical course consisted of eight practical demonstrations, as follows:

*First day:* A general discourse on anatomy, and the common teguments and muscles of the abdomen, by James Hamilton, the Deacon.

*Second day:* The peritoneum, omentum, stomach, intestines, mesentery, and pancreas, by John Baillie.

*Third day:* The liver, spleen, kidneys, ureters, bladder, and parts of generation, by Alexander Monteth.

*Fourth day:* The brain and its membranes, with a discourse of the animal spirits, by David Fyfe.

*Fifth day:* The muscles of the extremities, by Hugh Paterson.

*Sixth day:* The skeleton in general, with the head, by Robert Clerk.

*Seventh day:* The articulations and the rest of the skeleton, by James Auchinleck.

*Eighth day:* The epilogue, by Dr. Pitcairne.

Later the course was extended to ten days, and about the year 1705 arrangements were made with one man to take over the conduct of these lectures, and Robert Eliot was chosen as "public dissector," receiving from the town council a salary of £15 per annum, "as an encouragement to young men to study anatomy instead of travelling to foreign universities, which was attended by expenses and perils to youth." Eliot was succeeded by John M'Gill and Adam Drummond, who in 1719 resigned in favour of Alexander Monro, a young man who had a special knowledge of anatomy, having studied under Cheselden in London. On March 14th, 1722, Monro's appointment was confirmed by the town council for life. Monro lectured in the Hall of the Surgeons from 1719 till 1725, when, following upon a public riot directed against body-snatching, he removed his preparations for greater security within the walls of the University, as the Tounis College had come by this time to be called. As early as 1711 there had been great complaints of graves in Edinburgh being rifled,

FIG. 3.—Archibald Pitcairne.

and the Incorporation of Surgeons had felt themselves called upon to forward to the magistrates a memorial in which they denounced this as "a scandalous report most maliciously spread about the town," and entreated the magistrates to exert their utmost power for the "discovery of such atrocious and wicked crimes." The whole memorial, however, sounds rather exculpatory than sincere, and the practice probably continued, though with greater precautions. After the trouble of 1725 the Incorporation promised a reward of "five pounds stg., for discovering such as have given just ground for this report, whether they be Chirurgeons' apprentices or others personating them in their rambles or using this cover for executing their other villainous designs." There are, however, records which give some colour to these reports: for example, in 1724, after a woman had been executed, there ensued a fight between her friends and some surgeon apprentices for possession of the body. In the middle of the fracas the supposed corpse came to life, and lived for many years, with the popular appellation of "half hangit Maggie Dickson." It was not till a century later that the report received dreadful confirmation in the revelations at the trial of Burke and Hare.

Monro (*primus*), when appointed professor of anatomy, immediately introduced an extended course of instruction lasting from October to May, and including the history of anatomy, osteology, demonstrations on the soft parts and organs of the body, the dissection of various animals, the diseases for which surgical operations were commonly undertaken, and general lectures on physiology. This comprehensive course was continued every winter for nearly forty years, a period during which the number of students attracted to Edinburgh yearly increased. In 1720 the number attending the anatomy class had been 57, and by 1760 the annual number had increased to nearly 200.

Between these dates and shortly after the final appointment of Alexander Monro as permanent professor of anatomy, the town council decided, on the recommendation of the prominent medical men in Edinburgh, to appoint other professors, so that a complete medical course might be formed at Edinburgh. Dr. Crawford had already been appointed professor of chemistry in 1713, owing to the importance which this subject had attained in the hands of Sylvius and others on the Continent, and the final step in the institution of the school was made in 1726 by the appointment of Andrew St. Clair and John Rutherford as professors of medicine and institutes of medicine, Andrew Plummer and John Innes as professors of chemistry, and Joseph Gibson as professor of midwifery. The bicentenary of this foundation of the Medical Faculty at Edinburgh University was celebrated in June, 1926, and a full account appeared in the *BRITISH MEDICAL JOURNAL* of June 19th, 1926.

### THE HEALTH OF THE SCHOOL CHILD.

In presenting his annual report as the chief medical officer of the Board of Education for the year 1925,<sup>1</sup> Sir George Newman states that in all new public services, but especially in those of which the cost tends to increase from year to year, it is essential from time to time to examine the position and balance the cost against the benefit obtained. This he does for the school medical service for the year in question, making comparisons with previous years.

The duties of the school medical service fall under three headings: inspection for the discovery of defects and disease; curative measures; and preventive measures. For these purposes there are doctors, dentists, nurses, and clerks, with premises and equipment. The work of inspection includes the routine medical examination of three age groups, or one-third of the children every year; examination of special cases outside these age groups, and the following up and re-examination of those suffering from defects. The ostensible object of the work is to fit the child there and then to receive and benefit from the education provided for it by the State. But the crucial test of the service is not the cure year by year of so many children

suffering from ill health or defects of physique. The service is educational, and that is one reason why it falls within the duty of the local education authority.

The Act of 1907 did not require that only sick children should be selected for inspection and treatment, but laid down the great principle that every child, sick or well, should come periodically into the doctor's hands, in order that this process of health education should be available for all. Education in health involves the organization of the prevention of infection at school. It is concerned with the nutrition of the child, with games, with school work, rest, cleanliness, habits of life, with drains, light, warmth, and air. It seeks to get a clean body for the child, but, better still, to teach parent and child to keep the body clean. There are some 5,000,000 children on the rolls of the elementary schools in England and Wales. Last year 2,619,350 were examined—more than the half of all, and nearly 200,000 more than the previous year. The number found to require treatment apart from uncleanness and dental defects was nearly half a million, or 23.8 per cent. of all those inspected. Of the defects requiring treatment (excluding the two named) those of vision head the list, closely followed by enlarged tonsils and adenoids and other throat affections. Deformities account for a tithe, and tuberculous lung and local affections for still fewer.

Much of the success which has attended this work is due to the part taken by voluntary workers through the teachers and care committees. The influence the teachers can exert, and do in fact exert, on children and parents is unequalled; the success of many treatment schemes depends largely upon them. In London alone there are 330 school care committees, with 5,700 voluntary workers who give up their time with enthusiasm to the care of school children. They follow up individual children, secure regular attendance at the treatment centres, and see that the orders of the doctors are carried out in the homes.

Last year at least 80 per cent. of the children suffering from defective vision obtained proper treatment. Enlarged tonsils and adenoids required operation in 134,880 children, and 45 per cent. received treatment by operation—an increase on last year. Of the total roll of children 2,038,988, or two-fifths, were subjected to dental inspection, and two-thirds of them needed treatment; the number actually treated was 768,146, or 55.5 per cent. of those examined and found in need of treatment. School nurses made thirteen million inspections of children in the schools in regard to cleanliness—that is, three examinations for each child on the rolls. Those found to be unclean numbered 800,000, or 6.5 per cent.—the lowest recorded figure. Last year it was 1 per cent. higher. A sixth of these were cleaned under arrangements with local authorities, most of these being in London.

In secondary schools the incidence of defects of vision is somewhat higher than in elementary schools; defects of ear, nose, and throat are noticeably fewer; deformities are higher, but most are minor degrees of lateral curvature and flat-foot, not recorded in elementary school inspections.

### The Teaching of Hygiene.

There is gratifying evidence that the majority of the training colleges for teachers now realize that the study of hygiene is best approached through a general scientific foundation which includes biology, chemistry, and physics. The whole theory of hygiene is founded on these. The study of animal life enables students to obtain a knowledge of structure and action of the body which should be part of the mental equipment of every man and woman. In one modern training college last year 79 per cent. of the students took such a course of study. In addition to internal lectures and practical work, external lecturers gave accounts of social activities, and visits were made to special schools, clinics, model dairies, crèches, and other centres of welfare work. In the schools also there is evidence that more teaching is given in hygiene. Some school medical officers, notably Dr. Bullough of Essex and Dr. Savage of Somerset, report that definite instructions have been given for this teaching on the lines issued to all head teachers. Special lectures have been given by Red Cross and voluntary aid societies, particularly in connexion with women's institutes, and to officers of girl guides.

*Physically and Mentally Defective Children.*

The provision for the education of defective children incapable of taking advantage of the teaching of the ordinary schools is one of the most onerous tasks that the local education authorities have to undertake. Places are now provided for 45,000 children. Over 16,000 of these are for mentally defectives. Next comes the provision for crippled children, closely followed by the open-air schools for the sickly and schools for the blind and deaf. There has been an increase under nearly all these headings, but this is not due to any increase in the actual number of defective children, but to improved arrangements for the ascertainment of existing defectives. Generally speaking, there is sufficient provision for all children totally blind or deaf, but a considerable increase is needed in the provision of special classes for children who are partially blind or deaf. There is only about half the necessary accommodation for mental defectives, there is not enough for the epileptic, and there is pressing need for further provision for children in various stages of crippling, whether due to tuberculosis, paralysis, heart disease, or other cause.

*Open-air Schools.*

Reports from areas where open-air schools have been established show that they are taking a useful place in our educational system; the children benefit both physically and mentally from attendance thereat. Dr. Wyche of Nottingham says:

It is noteworthy that widespread outbreaks of "cold," influenza, and other infectious diseases, which not uncommonly play havoc in the ordinary schools, are never able to get a firm grip on the delicate children in the open-air schools; odd cases occur, but that is all; there is little or no spread of infection in sunshine and open air.

The returns of the results achieved are held to be useful as far as they go, but it is thought desirable to obtain further evidence as to the permanency or otherwise of the benefit received. The cost of the schools is high—£30 a year for each child in a day open-air school, as against £12 in an ordinary elementary school. The high cost is due to small classes, more teachers, three meals a day, and equipment for rest and for shower baths. Certain school medical officers in areas where such schools have been in existence for some years were invited to furnish reports of the after-effects. Returns were received relating to 231 children who had been for three or more years in such school. Their state three or more years after leaving was noted as follows: Very satisfactory 116, satisfactory 55, fair 27, unsatisfactory 21, still under treatment 10, dead 2; of 101 returned to the ordinary schools 81 are reported to attend regularly. Dr. Thomas notes that in his London district the after-history of the boys is more satisfactory than that of the girls, and suggests that the reason is that the home life and occupational activity of the girls are more confined than in the case of the boys. It is added that there are two chief influences that tend to depress the health and undo the good of the open-air school: first, unsatisfactory home conditions, and secondly, unsuitable employment. Attempts are being made to provide more suitable occupations, but the difficulty is to find work that parents think holds out good prospects, and especially of a type they know themselves. Dr. Auden of Birmingham reports that the gain derived is not only to health and physique, but is educational also. There would appear to be a definite financial advantage to the community, inasmuch as these children are enabled to become regular wage-earners when their school days are over.

*Juvenile Employment.*

The battle for the school child in relation to employment in industry has been fought and on the whole won through legislation that culminated in the Education Act of 1921, Part viii. No child may now be employed for gain under the age of 12 years. A child between 12 and 14 may be employed after school hours till not later than 8 p.m. The child is examined by the school doctor as to physical fitness before being permitted to take up the proposed employment, and in some areas close vigilance is exercised on the children in employment. Generally speaking, the opinion of the school doctor appears to be that under the present restrictions industrial employment to children over 12 years

out of school hours is not detrimental. Much of the work is out of doors, and the effect, both direct and indirect, is advantageous—for example, the child gets better food and clothing. But there are references to the innumerable cases where girls are used as drudges in the home, with disastrous results, both to health and mentality. This is a problem the solution of which lies in the development of an enlightened public opinion.

*Costs.*

The cost of the school medical service for the year was £1,300,347; this is about 2½ per cent. of the cost of public elementary education, which is just over 57 millions. So that of every £100 spent by local education authorities £2 5s. 2d. goes to the medical services—not a high premium of insurance. Sir George Newman states that he has

"no doubt whatever that the nation is getting value for money. A very large number of children suffering from defects of various kinds are having those defects remedied and are thereby enabled to profit more fully from the education provided for them at the public cost. These children are the workers and citizens of the future, and improved physical condition now means increased efficiency and capacity in later years. These are positive gains, and to them must be added the large saving of expenditure which would otherwise have been incurred in various ways had these defects and this physical unfitness been allowed to remain."

*Infants.*

One significant fact that has emerged through systematic school medical inspection is the serious degree of physical defect in the children on their first admission to school. This the report places in the forefront of the medical problems of the elementary school. Observations have been taken of the state of entrants over a number of years. Broadly speaking, there is not much evidence of substantial improvement—nothing like the manifest improvement of the children in school. This is due to the fact that for the most part many of them had never had medical attention or even examination until they were brought to the school for the first time. There is, however, one criterion worthy of note—namely, general physique as measured by height and weight. Dr. Wheatley of Shropshire reports an improvement in weight since the war in both sexes, of entrants and leavers, in town and country schools. Dr. Herdman of Bedfordshire says that children born in 1920 and examined in 1925 averaged nearly one inch taller and one pound heavier than the average pre-war child of the same age. Dr. Thomas of Acton gives similar returns, and adds that the full returns show that the increase in height and weight is more obvious among the children coming from the schools in the poorer districts. Malnutrition, large tonsils and adenoids, bad teeth, deformities, and squint are common findings. The medical observations are held to represent a large measure of failure wisely to provide nurture for the early years of infancy. Much of the failure is not due to neglect or want of effort. It may be due to overanxiety for the welfare of the child showing itself in overfeeding, overclothing, and over-coddling generally. In either case it is want of knowledge in the grand art of child nurture. The cure for this is thought to lie in a closer association between the infant welfare work and the school medical service, but the private medical practitioner and the voluntary hospital are also rendering most valuable assistance.

It is suggested that it would be of value if each school medical officer in his next yearly report reviewed the health of the entrant child in his area and indicated any special problem with which he is faced. Information and observations bearing on the physical condition of the entrant in relation to the care bestowed during pre-school years, together with an indication of the results already attained, might prove invaluable in affording guidance in regard to different types of measures adopted or required. With a view to elucidating the interpretation of cause and effect of early disease in the young child Sir George Newman is obtaining the aid of individual medical officers in regard to the more detailed examination and following up, personal and environmental, of certain children immediately on admission to school, with the object of ascertaining, in regard to physical defects present, their relative frequency and importance, their causation, their subsequent history, and the measures to be taken to prevent their occurrence.

(To be continued.)

## Nova et Vetera.

### THE MEDICAL ART CALENDAR.

For some years past we have noticed briefly at this season the *Medical Art Calendars* published by Mr. J. Philip Kruseman at the Hague. A copy of the ninth annual issue of this calendar, for the year 1927, has now reached us. It is quite up to the standard of its predecessors, both in the choice of pictures and in the skill and taste with which they are reproduced. In selecting his material Mr. Kruseman has been assisted by a small advisory committee of three Dutch medical men and a dental surgeon; while on the historical and artistic side he has again had the help of the eminent art critic Dr. Hofstede De Groot.

Among the artists whose work excellent examples are presented this year are Jan Havicksz Steen and Pieter Brueghel the elder, and the front cover reproduces on a larger scale the better of Steen's two pictures of a doctor

visiting a lovesick young woman with chlorosis. Many other Dutch painters of the sixteenth and seventeenth centuries are represented, together with a few Flemish artists of the same period. Oil paintings predominate, but several reproductions of old engravings appear; for instance, the frontispiece of the *Fabrica* of Vesalius by Nicolaas Fontanus; one of a set of engravings illustrating the five senses, by David Teniers the younger; and a portrait of Carolus Clusius, professor of botany in the University of Leyden at the end of the sixteenth century. There is also an early Italian woodcut of the martyrdom of St. Apollonia, the patron saint of dentists, and a modern steel engraving after Bisschop's picture showing Rembrandt before the door of the anatomical theatre at Amsterdam, where he was making studies of his friend Dr. Tulp and his pupils for "The Lesson in Anatomy."

Most of the pictures are intimate character groups having a medical interest, direct or indirect, and doctors and dentists and their patients again form the staple of the collection. The store of Dutch pictures dealing with medical incidents seems almost inexhaustible, and it is interesting, year by year, to observe how different artists at different periods have handled the same kind of subject. Thus in the present calendar we see the village surgeon pulling off a plaster from the arm of his wincing rustic patient, vividly depicted by Adriaen Brouwer (1606-38), and can contrast it with Lucas Van Leyden's drawing of an operation upon the ear, a century earlier. Uroscopy, always a favourite theme with the painters of Dutch "medical interiors," is the subject of two illustrations, and it will be noted that Jan Steen shows the doctor inspecting a common short-necked urine bottle, while Bernard Van Orley, in his fine study of Job's trial by sickness, makes the physician hold a long-necked urinal.

The picture from this year's *Calendar* here reproduced is a photograph of the entrance to the former pest-house at Leyden, with the sculptured group by Verhulst over the doorway. This stone carving bears the date 1660, and the child in its grandmother's arms has doubtless just died of plague. The grief-stricken mother, with her younger infant tugging at her robe, is finely portrayed.

These calendars are a distinct contribution to the history of medicine, and there must be a good many of our readers who would like to have a handy means of preserving the

illustrations after the almanacs have served their turn. They may be glad to know, therefore, that Mr. Kruseman is preparing a special album in which the pictures from this and previous calendars may be collected.

The price of the *Calendar* is 6s., post free, and the album will be sold at 2s. 6d. The pictures illustrating former issues are obtainable also from the publisher at 'S-Gravenhage, Noordeinde 91, Holland.

### THE FATHER OF TRIGONOMETRY.

RICHARD OF WALLINGFORD, the great fourteenth century mathematician and astronomer, whose election six hundred years ago to be Abbot of St. Albans was celebrated last week, was a leper. No doubt the term was applied loosely in that age to include various chronic skin diseases, perhaps psoriasis in particular. But it seems pretty certain that the disease he had was leprosy, for in a prayer composed by him when Abbot he spoke of God's great bounty in inclining "the hearts of the great towards me, that ever when present, they do not abhor my speech and the deformity of my face and hands, but rejoice to converse with me." The mention of deformity of the hands seems to prove that he had something worse than a disease of the skin only. Also in the prayer he speaks of himself as "of lowly estate and smitten by Thy providence with an evil plague, so that I am not worthy to walk among men, but should by law be cast without the camp. Dr. R. T. Gunther of Oxford, who has transcribed the passage in a recent article in *Nature*, states that there are two miniature portraits of Richard in the illuminated chronicle of Matthew Paris, and that in both he is represented with a spotty face. Richard was the son of a blacksmith, and the training he is assumed to have had in the smithy is thought to have stood him in good stead when he set to work on the instruments, the alabon and the rectangulus, for which he is still remembered. The two instruments, Dr. Gunther thinks, were intended to be used together. The second instrument was designed to simplify the means of determining the course

The Old Pest-house, Leyden.

and place of fixed stars and planets.

Richard, who was born in 1291, was adopted by the Prior of Wallingford, who sent him to Oxford at the age of 17. In 1314, when aged 23, he became a monk at St. Alban's Abbey, but after three years the Abbot sent him back to Oxford as one of the students every Benedictine House was bound to maintain at the University, so that the Order's reputation for learning should be maintained. He entered the newly founded college of Merton, the home of the newer learning, and there found several kindred spirits in the study of mathematics and the observation of natural phenomena. No doubt Richard's main or early interest was in astrology, but, as his work showed, his mind was cast in the scientific mould, and he was ready to seek practical applications. His administrative ability must indeed have impressed his contemporaries, for not only was he elected Abbot of St. Albans in 1326, when only 35, but later on he became a trusted adviser of the King, who took up the cudgels for him when some of the monks of St. Albans, not liking his strict discipline, mutinied when he was discovered to be a leper, and appealed to the Pope to deprive him. The attempt failed, but Richard died in 1335 at the age of 43, after the abbot's house in which he was sleeping had been struck by lightning. Dr. Gunther thinks that in his weakened health the shock was fatal.

## THE NEED FOR THE USE OF DOGS IN PHYSIOLOGICAL AND THERAPEUTIC EXPERIMENTS.

At one of its recent meetings the Science Committee of the British Medical Association considered and approved the following Memorandum, setting out briefly reasons why it is essential that dogs should be used for certain classes of physiological, pathological, and therapeutic experiments. The publication of the Memorandum at this time may be helpful to members of the Association, who, owing to the recent incident in connexion with the Physiological Institute of University College, may have present occasion to consider the subject and possibly to advise members of the lay public upon it.

### MEMORANDUM BY THE SCIENCE COMMITTEE OF THE BRITISH MEDICAL ASSOCIATION.

The modern science of physiology started only in the second half of the last century. The early workers devoted themselves to the establishment of the general principles of physiology. They did not know what the practical therapeutic results of their work would be, but they knew that advance in therapeutics could come only as a result of increase of knowledge of the functions of the body.

Claude Bernard in 1877 said, regarding the practical therapeutical value of his work on the function of the liver in relation to sugar metabolism and diabetes: "Sans doute, nos mains sont vides aujourd'hui, mais notre bouche est peut-être pleine de légitimes promesses pour l'avenir." His work established the fundamental facts regarding the manner in which the transport of sugar in the body was affected. It had no immediate practical therapeutic value, but it formed the foundation for all future work on the subject; after forty-four years Claude Bernard's prophecy was fulfilled, and the invaluable remedy insulin was discovered by Banting.

To-day we have a knowledge of the fundamental processes of many physiological functions, thanks to the pioneer workers of the past. The present century has already reaped a brilliant harvest of practical therapeutic results from researches conducted during last century from a purely theoretical interest.

Insulin is a striking example of long years of research being finally crowned with a brilliant success of the highest therapeutic importance. Numerous other examples of a less striking nature could be mentioned. The knowledge of the importance of vitamins in nutrition was the result of academic work carried out at the beginning of the century, and now it promises to be of the most fundamental importance in the prevention of disease amongst urban populations.

A great many problems which at present appear of purely abstract interest are still awaiting solution, and it is as necessary as ever, if the foundations of therapeutic science are to be strengthened and enlarged, that these should be solved. Nevertheless, the knowledge which we already possess is sufficient to permit animal experiments to be made on definite problems connected directly with the healing art. That is, it is intended to utilize our knowledge regarding general physiological and pathological laws to improve the treatment of disease.

For this detailed work it is essential to use animals as nearly allied to man in their metabolism as possible, and the only alternative to this is to make experiments on man himself. The latter is a last resort, but it is unavoidable in diseases which are not transmissible to animals, as in dengue fever; in this instance 64 volunteers were inoculated with dengue from mosquitos (*Journ. Amer. Med. Assoc.*, 1926, p. 418). Similar experiments have been made in respect to malaria and yellow fever, not without risk to life. Furthermore, when it is desired to make experiments to determine the value of a specific therapeutic method it is essential that they be made on a large number of experimental animals, with many controls. This is necessary to avoid the results being vitiated by individual variation.

These reasons make the use of dogs necessary in experiments, because no other suitable animals are available. Healthy monkeys in large quantities cannot be obtained in

this country. In herbivorous animals, such as sheep and goats, the physiological functions of the body are too dissimilar from those of man. The diet and metabolism of the dog are almost unique in their similarity to those of man. For example, a cat cannot be fed on a diet of biscuits or a rabbit on one of meat, whilst a dog can be given either, or an intermediate diet. Experiments on dogs may therefore throw light on human conditions—for example, with regard to digestion and urinary secretions—which would not be valid in any other available animal. Questions of mere size often preclude the use of cats. Speaking generally, the more experiments are directed to obtain results of immediate therapeutic importance, the more are experimenters forced to use dogs. This is seen very clearly if the recent work which has led to results of immediate therapeutic value is considered.

#### Insulin.

The fundamental work was all done on dogs by Banting and Best.

#### Heart.

All the recent advances in knowledge concerning the mode in which functional disorders of the heart arise was done on dogs. Our knowledge of the functions of the spleen and the mechanism of the secretion and absorption of the cerebro-spinal fluid is also due to experiments on dogs.

#### Parathyroid Glands.

The disease of infantile tetany has long remained a mystery, but it has been known to be associated with certain minute glands, the size of a pin, embedded in the thyroid gland. Collip has now shown by experiments on dogs that these glands have a most important action in controlling the calcium content of the blood. He has obtained an extract which has been used with therapeutic success in infantile tetany. It is possible that this extract will be found of the greatest value in the treatment of many forms of septic troubles—for example, wounds and ulcers that refuse to heal.

#### Rickets.

This disease used to be known on the Continent as the "English disease." It has long been a dreadful scourge in the children of the large cities of England and Scotland. At last its causation is known, and it is now recognized that it can be cured either by the administration of cod-liver oil or by exposure to sunlight. Of these two cod-liver oil is the more important, because one can buy cod-liver oil but one cannot buy sunlight—at least not in Glasgow. The fundamental work on the relation of cod-liver oil to rickets was done on puppies, because in them it is possible to induce rickets. The work on light was done chiefly on children.

#### Dentition.

Decayed teeth are still one of the chief causes of ill health in this country. The recruiting figures bear eloquent testimony to this fact, while the cost to the country of dental clinics is not inconsiderable. Mrs. Mellanby's work on puppies showed that a slight deficiency in the fat-soluble antirickets vitamin is a potent cause in favouring teeth decay. This work could not have been done on any other animal, and as a result of it we have a method by which the dentition of young children may be greatly improved.

#### Liver and Bile.

Liver diseases are one of the most important classes of disease in this country. Our knowledge of the functions of the liver, which is by far the largest and most important gland in the body, is absurdly deficient. In the case of jaundice it was not even known if this condition was always due to liver disease or whether it might not also be due to blood disease. Prolonged experiments on dogs by Mann in America have shown that jaundice can be produced not only by liver disease but also by certain diseases of the blood. This is the first step towards the discovery of the causation of jaundice, and hence to the discovery of the means for its prevention.

The liver excretes bile in quantity only less in daily amount than that of the urine. But whereas the urine is discharged into the open, the bile passes into the intestine, where it disappears as such, partly mingling and discharged with the faeces, partly reabsorbed into the circulation.

Owing to our lack of knowledge of the functions of the liver and bile, the disorders and diseases connected therewith continued to be subjects of conjecture until recently. The ancients deemed the liver the principal organ of the body and the focus of all its activity; Harvey's experiments demonstrated that the ancient view was to a large extent erroneous; Glisson showed us something of the structure of the liver; and *post-mortem* examinations demonstrated the changes in the liver which end in death, but afforded no light on the causes of these changes, which may possibly be amenable to remedy.

The experiments of Claude Bernard already referred to started inquiries relating to the real function of the liver. Complications of disease had produced biliary fistulae, which exhibited the large amount of bile daily excreted; but with this concurrent abnormality—that the bile was escaping externally and not into the intestine.

#### *Surgery of the Gall Bladder.*

Advances in surgery were preceded by animal experiments showing that the gall bladder might be excised without harm. By further steps the removal of gall stones from the biliary passages was firmly established as a means of preventing fatal inflammations or the supervening of cancer. But there continued obscurity as to the indications for surgical interference, with the result that there was delay in carrying out operations, or the surgeon had to undertake exploratory operations while uncertain as to the conditions needing to be remedied.

In the course of pharmacological experiments carried out on dogs, certain new chemical preparations have been discovered to be excreted by the liver into the bile without being poisonous to the animal. Moreover, when excreted into the biliary tract these preparations prove to be opaque to the  $x$  rays. Thus by injecting dogs with the preparation and observing the animals under  $x$  rays, the gall bladder can be seen to be filled with material causing it to be exhibited in a skiagram as a black object. Also the course of the bile can be traced by these shadows through the common bile duct into the intestine. The excretion of bile into the intestine can be demonstrated to be increased by a drug, such as magnesium sulphate taken by the mouth, when it reaches the biliary orifice in the duodenum. Such experiments, first carried out on dogs, have already brought about improvements in surgical treatment. The chemical preparation injected into the patient causes no essential disturbance; the free excretion of bile into the biliary tract and its discharge into the intestine in the healthy subject can now be compared with the different varieties of obstruction in the biliary passages. Gall stones in the gall bladder or bile ducts are composed of material translucent to  $x$  rays, which cause no shadow; they are now made apparent as clear rounded areas in the midst of a dense black shadow. The surgeon can now be furnished with information as to the exact position of a gall stone, or a biliary obstruction, before commencing the operation. The most approved preparation at the moment appears to be tetraiodophenolphthalein-sodium, administered either by the mouth or by intravenous injection.

#### *Distemper in Dogs.*

Continuous research is going on, and valuable results have already been obtained. The problem is very difficult, but there is every reason to hope for ultimate success. Success will probably throw light not only on distemper but on a number of obscure human diseases.

#### *Pregnancy and its Disorders.*

Pregnancy and its disorders in general are very difficult to investigate. The bitch is particularly suited for this study, as the relations between mother and foetus are more like those found in the human species than they are in those of herbivorous animals. The cat is here too small and temperamentally unsuitable, while monkeys rarely breed in captivity. Our knowledge of the influence of the ovaries on the sexual cycle and the mechanism of uterine contraction is the outcome of experiments on dogs.

#### *Anaesthetics.*

Dogs are best anaesthetized without causing fright or discomfort by means of chloroform. But they are very

easily killed by an overdose in the hands of an inexperienced administrator. An investigation of the cause of this death, produced more readily in the dog than man, has led to invaluable information, and demonstrated the action of chloroform on the vagal system.

#### *Conclusion.*

Medical science cannot remain stationary; unless it advances it will cease to attract the best brains and will retrogress; freedom for research is essential. It is an impossible position if a scientist arrives at a point where the next step involves research on dogs and then has to stop.

Restriction will as surely kill research as the forbidding of dissection on human bodies in Mohammedan countries killed Arabic medical science, which—as a result of the knowledge obtained from Greek science, as advanced by experiment in Alexandria—was in the early Middle Ages far in advance of European medical science of the time.

## France.

[FROM OUR OWN CORRESPONDENT.]

#### *Summer Gatherings.*

Two fresh manifestations of the great activity prevailing in the medical profession in France were afforded this summer by the Journées Médicales de Paris and the Assemblée extraordinaire de l'Union des Syndicats. The journées were held in July, and the members met in the Grand Palais. As is probably well known, this type of meeting had its origin in Brussels, and it seems destined to have a wide extension. During the month of November this year the journées de Montpellier were held. They comprised lectures and demonstrations designed to give practitioners information of the latest progress made in the art of treatment, using that term in its widest sense. Professor Vidal, who is ever at the head of every modern movement, was the moving spirit of this gathering. It was not, however, because he is a university professor that he occupied the chair, but for the more splendid reason that he is the leading physician in France. Nearly two thousand persons attended, which, for a first meeting, was a very striking success.

The Union des Syndicats Médicaux made an attempt to define the attitude the medical profession in France should take in face of the new laws about social assurance which Parliament is about to adopt. By a very large majority it was decided that the members of the Union should refuse to collaborate in carrying out the law if the assurance was to be at the expense of the medical profession. In other words, while the practitioner does not wish to profit from the operation of the law, it is resolved to apply to all compulsorily insured persons the minimum syndicate tariff. Unfortunately the Union did not succeed in ending the conflict by which the 12,000 members of the Union are separated from 3,000 federated practitioners who have recently left it. Though the attempt at reconciliation failed, there never was a time when a united front was more desirable than the present.

#### *Congresses.*

Medical life, which during the summer seems to be so wholly concentrated in the thermal stations, begins again in Paris in October. It has been marked this year, as in previous years, by the congress of surgery in Paris. Its president, Professor Faure, in his inaugural address, which was delivered in the presence of representatives of the Government, did not hesitate to express his fear that the state of public opinion rendered the practice of surgery singularly difficult. He was referring to the frequency with which patients who had been operated upon, and were, sometimes perhaps quite honestly, dissatisfied with the results, instituted legal proceedings against the surgeon. Should a fracture, after consolidation, leave some functional defect, or should a scar be deemed unsatisfactory, a demand was made for at least pecuniary compensation. Only too frequently have the results of an operation, demanded for the relief of unbearable suffering, led to the unfortunate surgeon being treated as a malefactor. Burning words such as these, delivered with all the eloquence for which Professor Faure

is famous, have found an echo in the newspapers, and it is just possible that the general public has been made to understand that if a surgeon is to operate with a threat of this kind hanging over his head he will hesitate to accept the risk and feel inclined to leave nature to do its worst. The two chief discussions at the congress were on the pathology of the cartilages of the knee and the value of conservative operations in inflammatory lesions of the annexes. This last question is engaging a great deal of attention, and it is satisfactory to find how anxious French surgeons have become to avoid surgical procedures which produce mutilations that can never be remedied. The meeting of the congress of surgery was followed immediately by the congress of urology and the congress of hygiene. At both there were exhibitions, where those interested could readily make themselves acquainted with recent mechanical advances.

#### Students and Post-Graduates.

Every student to-day is impressed by the necessity of losing no time in completing his curriculum. The cost of living has become so high that many of our new students find that the least prolongation of the time of study beyond the period fixed by regulations is impossible. The time has gone when the newly qualified man could afford to spend many months in wandering from one special service to another. Nowadays he must begin at once to earn his living. Later on, perhaps, he will come back to the university; fortunately the universities are realizing the necessity of providing him with the intellectual nourishment of which he stands in need.

The most recent devices used in the schools combined to ensure ultra-rapid methods of teaching. Last year we saw how the cinematograph, combined with the loud-speaker, made it possible to give a simultaneous demonstration of a clinical case to an unlimited number of students. Recently we have had a striking example of this tendency in a demonstration given at the Faculty of Medicine by Dr. Lutembacher: the telecardiophone had proved to us that the presence of the patient was unnecessary, because the sounds were fully registered by the instrument. By carrying the method to its extreme limit Dr. Lutembacher has succeeded, by explanations given through the loud-speaker, in synchronizing what the eyes see and what the ears hear. Some of us wonder whether he has reflected on the possibility that the loud-speaker may in the future allow us to do without the presence of the teacher!

G. MONOD.

## England and Wales.

#### SHEFFIELD MEDICAL DINNER.

THE Sheffield annual medical dinner was held at the Royal Victoria Hotel on November 25th, the chair being taken by Dr. C. J. Patton, professor of anatomy in the University. An even larger number than last year attended, and the guests included the Master Cutler, who, in replying to the toast of "The City and Trade of Sheffield," spoke in high terms of the administrative and medical work of the city. Canon Dolan proposed the toast of "The Medical Profession," and contrasted the prevalent want of settled convictions and definite purpose in the general population with the high ideals, faithfulness to famous traditions, and strong discipline of the medical profession. Sir Thomas Horder, who was the principal medical guest, replied to this toast, and congratulated the Sheffield practitioners on their loyalty to medicine as a profession. Elsewhere he had detected recently signs of laxity in the maintenance of dignity, and even a gratuitous desire to shed traditions which for very many years had endowed the work of the medical profession with nobility and greatness. There was some danger that a craving for publicity and selfishness might diminish the respect in which the profession was generally held. It had in the past been a simple matter for the public to distinguish between a qualified and an unqualified practitioner, and it was in the public interest that this distinction should remain clearly defined. There was some tendency at present to distinguish only between the unsuccessful and the successful unqualified man, rather than

to take account of whether he was qualified or not. Referring to the relation of the medical profession to the public, Sir Thomas Horder said he believed that the only sound way of protecting the citizen was the maintenance of personal contact between patient and doctor.

#### AFTER-HISTORY OF TUBERCULOUS PATIENTS.

The Public Health Committee of the London County Council has presented a report on the after-history of tuberculous patients who received residential treatment under its scheme and were discharged during 1922. The particulars have been collected from reports on the patients obtained approximately three years afterwards. The number of adults discharged during 1922 was 3,636; of these, 182 were not traceable, and in 270 others the diagnosis of tuberculosis was not confirmed. Of the 3,184 cases investigated, 2,957 were pulmonary. These had been classified during treatment into two main groups: A, cases in which the tubercle bacillus was not found in the sputum, and B, in which it was; the latter group had been subdivided into three groups: (1) cases with slight constitutional disturbance, if any, and with obvious signs of very limited extent; (2) cases which could not be included in this first subgroup, but were not sufficiently advanced to be included in (3), which consisted of cases of profound systemic disturbance or constitutional deterioration, and all cases with grave complications:

#### Condition Three Years Later of Patients Discharged in 1922.

| Group.       | Total. | Percentage Alive. | Percentage Dead. |
|--------------|--------|-------------------|------------------|
| A ... ..     | 409    | 87.0              | 13.0             |
| B (1) ... .. | 279    | 74.2              | 25.8             |
| B (2) ... .. | 1,440  | 48.0              | 52.0             |
| B (3) ... .. | 829    | 8.7               | 91.3             |

An investigation of the fitness for work of the 1,510 surviving patients showed that, out of a total of 563 A and B (1) cases, 63 per cent. were at work; the percentages of survivors at work in the B (2) and B (3) groups were respectively 23.6 and 16.7. Similar investigations were made in the case of 578 children—326 with pulmonary and 252 with non-pulmonary (surgical) tuberculosis—discharged during 1922, and the results were as follows:

| Group.               | Total. | Deaths up to three years after discharge. |
|----------------------|--------|---|
| A ... ..             | 213    | 1.6 per cent.                             |

#### MEDICAL DEVELOPMENTS IN MANCHESTER.

In view of the increasing importance of nerve work and the need for specialization in this branch of surgery, the Manchester Royal Infirmary is proposing to create a new office. A neurological surgeon is to be appointed with charge of hospital beds and out-patients specially reserved for this class of work. The laboratory of clinical research at the Infirmary has now been running for twelve months under the new director, Dr. W. M. Roberts. Much useful research work on the alimentary canal is in progress.

The post-graduate lectures at the different hospitals are in full swing, and, judging by the attendance, appear to be much appreciated by the local practitioners. A scheme has been under consideration for some time whereby it is hoped that Manchester will shortly be well to the forefront as a centre for post-graduate teaching. This scheme will be quite distinct from the undergraduate teaching so far as the actual instruction is concerned. It is proposed to hold short courses of three months in special subjects, whilst in addition intensive courses lasting for three weeks will also be held. The University and the leading hospitals are actively co-operating in this plan, and it is probable that the present post-graduate courses of lectures will be linked up in one big scheme. The course may be launched next autumn, and it is hoped that practitioners from the colonies and abroad will be attracted by the syllabus. Manchester has a rich supply of clinical material and offers excellent facilities for a course of this nature second to none in the country. The new Vice-Chancellor, Dr. W. H. Moberly, has thrown himself with

great enthusiasm into the work of the University, and appears to be taking special interest in the medical school. This was seen at the opening meeting of the Medical Society, when he presided during the delivery of the presidential address by Dr. A. A. Mumford.

Manchester, and more especially the Royal Infirmary, has recently suffered a great loss in the death of Sir William Cobbett in his eighty-first year. Sir William became chairman of the board of management of the Infirmary in 1934, and largely inspired the removal of the hospital to the new buildings in Oxford Road. It was as a mark of his labours in this capacity that he received his knighthood in 1939.

#### WIGAN INFIRMARY.

The new radiological department at Wigan Infirmary, which has been established at a cost of about £10,500, was opened by Dr. Robert Knox on November 16th. The new building contains rooms for radiographic diagnosis and treatment and two rooms for heliotherapy. Great care has been taken to make the department as completely up to date as possible, and special attention has been devoted to protecting the operators and the patients. Dr. Knox delivered an address on the advance of radiology, and emphasized the importance of close co-operation between the general hospital staff and the radiologists. The powerful apparatus which had been installed would make it possible to treat all forms of malignant disease, and he was glad that the bulk of the apparatus was British. The chairman stated that over £60,000 had been spent in the establishment of new departments at the Infirmary during the past ten years. He claimed that the operating theatres were the finest in the country.

#### BRITISH DENTAL HOSPITAL.

The annual meeting of the British Dental Association was held at the house of the British Dental Hospital on November 25th. Sir Harry Baldwin, who presided, said that last year the British Dental Hospital had treated about 20,000 cases. It ramified into various parts of London, and had five chief hospital centres and also dental clinics in populous districts. The hospital was opening new centres, and negotiations were proceeding with regard to the opening of yet others. The hospital represented in the true sense of the word a public dental service. The service was rendered by dental surgeons to a great mass of the public who, while able to pay something towards the cost, were not able to afford the customary fees. On that basis the hospital had been able to pay its way. The dental surgeons on its staff, of whom there were between forty and fifty, and the anaesthetists, of whom there were about fourteen, practically did their work for love, except for a small allowance for expenses. The service was not restricted to insured persons or to children, but was open to all persons whose means were insufficient to meet the ordinary cost of dental treatment. The hospital also engaged in propaganda and instruction in dental hygiene. He announced that the Duchess of York had consented to succeed the late Queen Alexandra as patroness. An address was then delivered by Colonel T. A. Hunter, C.B.E., dental director for New Zealand. Colonel Hunter described how, following upon the war, which had revealed a good deal of dental deficiency, the New Zealand Government instituted a scheme for the prevention and treatment of dental troubles in school children. On instituting the scheme it was found that no less than 85 per cent. of the children required some form of treatment. It was resolved to aim at prevention in young children, and to follow the children up as far as possible throughout their school life. To this end a service of specially trained dental nurses was established to undertake dental supervision of the children. These young women received two years' training, and they started work at a minimum salary of £195, rising to £225. Professional interests were carefully safeguarded, and the dental nurses were not allowed to practise outside their sphere, even in association with a registered practitioner. At the present time there were fifty of these nurses in the field and sixty probationers in training, and the Minister of Health of New Zealand was anxious that the numbers should be increased. The nurses were placed in the

schools as soon as their training was completed, and the children were examined every six months. At the present moment 30,000 children were under treatment or observation.

## Scotland.

#### RELATION OF VOLUNTARY TO MUNICIPAL HOSPITALS.

At a meeting of the Aberdeen Town Council on November 15th a letter received from the clerk of the Aberdeen Royal Infirmary was remitted to the Public Health Committee for consideration. This letter contained the observations of the honorary medical and surgical staff of the Infirmary with regard to the hospital proposals of the town council. The Infirmary staff expressed the opinion that the concentration of patients in one hospital area is of benefit both to patients and to medical students, and affirmed very strongly that the main venereal disease department should continue to be at the Infirmary, not at a special clinic; the staff also deprecates strongly the transference of cases of surgical tuberculosis, pneumonia, and other illnesses from the voluntary to the municipal hospitals, as proposed and practised in some areas.

#### LAND AND NATION LEAGUE.

Dr. Joseph Hunter, M.O.H. for Dumfries, has been appointed director in England and Wales for the work of the Land and Nation League. Dr. Hunter was approached some time ago to stand as candidate in the Liberal interest for Dumfries Burghs, but at that time preferred to exert his activities on behalf of Dr. Chapple, who was then with a parliamentary delegation in South Africa. It is expected that Dr. Hunter will be asked to contest the constituency in the Liberal interest at the next election. Dr. Hunter is a graduate in medicine of Edinburgh, and D.P.H. of Cambridge. He served in the South African war, and is a recognized authority upon the life and works of the poet Robert Burns.

#### SCOTTISH SECRETARY ON SOCIAL SERVICE.

The report presented to the annual meeting of the Edinburgh University Settlement, when Principal Sir J. Alfred Ewing presided, referred to an appeal for a sum of £50,000 for the purpose of rebuilding the settlement which had been issued shortly before the outbreak of the strike, and in consequence had not been pressed upon the public, although a sum of £5,547 had already been contributed. Sir John Gilmour, Secretary of State for Scotland and Lord Rector of Edinburgh University, said that when he was a student in the University the settlement did not exist, but when he passed to the University of Cambridge he was brought directly in touch with just such a movement as the present one. In certain directions some of the great English universities had been working at these problems for a longer time, but their importance was now recognized in other great centres of life. Everyone knew that there were differences in ability to reach the higher stages of education, but all true citizens recognized the importance of acquainting themselves with the conditions of life, circumstances, and lines of thought of those who moved in other spheres than their own. Many of those who had taken part in the great war had hoped that the very close and personal association which grew up between the leaders of the men in the field and the rank and file would break down many of those foolish misunderstandings of class distinction. A great deal had been done in this direction. The men and women students of to-day would be the leaders of the future, and the power of leadership must be acquired by knowledge of the circumstances of life in other quarters of the world.

#### HEALTH OF EDINBURGH CHILDREN.

A report submitted by medical officers of the Scottish Board of Health to the Public Health Subcommittee of Edinburgh Town Council states the results of an inspection dealing with the arrangements for child welfare in Edinburgh. The maternity and child welfare scheme is stated to be both effective and economical. There are some forty clinics, day nurseries, play centres, and other institutional advantages arranged for children. The total number

of deaths among children under 1 year of age during 1925 was 751, giving a death rate of 96 per 1,000 births, as compared with 69 in the preceding year. Provision has to be made in the various agencies for an estimated number of children under 5 years in the city amounting to 32,626. During the past year the health-visiting nurses paid 6,690 visits to newborn children, 64,123 visits to children between 1 and 5 years, and 1,312 visits to expectant mothers—a total of 72,125 visits, or an average of 3,606 visits by each nurse. The increased appreciation by the public of the advice given at ante-natal clinics is shown by the fact that total attendances at these during 1925 were 8,798, as against 7,769 for the previous year.

#### TOWN PLANNING.

A lecture under the auspices of the Edinburgh Women Citizens' Association was delivered on November 17th by Captain Reiss, chairman of the Garden Cities and Town Planning Association, London. He demonstrated, by means of photographs taken from the air, how the old plan of rows of monotonous and closely packed buildings, with little space between them, was being displaced by houses grouped in crescents and squares, in such a way as to ensure a maximum of sunlight and fresh air. Regard must be had also to industrial development, and schemes for neighbouring towns should be considered together. Additional land adjacent to new residential quarters might often be secured for factories, and in this way much expense saved in the matter of transport of workers. Until quite recently the artisan had never been properly housed as housing was understood to-day. Since the armistice the number of houses actually built in Great Britain had only just met the ordinary annual demands. Captain Reiss urged that schemes for slum clearance should be thought out well beforehand. He described a scheme in Bristol where half an acre of land was secured close to a slum area about to be cleared. Houses were built upon it into which tenants of the old houses were persuaded to remove, and their old houses were then demolished and rebuilt. Other tenants were then moved into the latter, and their houses in turn rebuilt. In this way, with a small area of ground, a considerable slum area could be replaced, and there were always a few empty houses to work upon.

#### BEQUEST TO INVERNESS INFIRMARY.

The directors of the Northern Infirmary at Inverness have received notice of a bequest by the late Mr. John Mackay of Montreal, leaving the residue of his estate, which is expected to amount to approximately £20,000, to the Infirmary. Mr. Mackay, who died in October, was a native of Inverness and went to Canada as a boy, and there built up a flourishing business as a stockbroker and banker. The directors of the Northern Infirmary are at present endeavouring to raise £100,000 for the purpose of erecting a hospital to meet the needs of the Highlands, and towards this sum £50,000, including Mr. Mackay's bequest, has already been received.

#### WELFARE CLINICS AND BIRTH CONTROL.

In an address delivered under the auspices of the Society for Equal Citizenship, on November 23rd, Dr. Joan K. Rose suggested that questions involving birth control could most suitably be considered at ante-natal clinics, and at these post-natal work should also be undertaken. In such a clinic the subject seemed to be placed in its proper perspective—as a small piece only of a complete maternity service whose aim was to secure the health of both children and mothers. A large family, the lecturer considered, was not in itself a thing to be avoided. The defect lay only in a large family of poor stock, below the poverty line, which was liable to be a hindrance to social evolution. Encouragement of a good stock should go along with discouragement of the bad.

#### HOSPITAL FOR INCURABLES, EDINBURGH.

The report presented to the annual meeting of the Royal Edinburgh Hospital for Incurables showed that the daily average of patients under treatment had been 201. At the end of the year there had been a waiting list of 56, of which 44 were women. The chairman, Sir Henry Cook,

said that the managers wished it to be clearly understood that patients were not admitted by rotation, but according to the urgency of their condition. The general hospitals, owing to the pressure upon their accommodation, could not retain cases of incurable disease, even when in urgent need of hospital treatment, and such cases were especially suitable for the Longmore and Liberton hospitals. The ordinary income for the year ending March 31st, 1926, had been £12,000, and the ordinary expenditure £18,756, the balance having been met out of capital. The average cost per occupied bed for the year in the two hospitals of Longmore and Liberton had been £85. Dr. William Robertson, medical officer of health for Edinburgh, said that the low cost per bed reflected very favourably upon the management, because, taking other large institutions in the city, this cost varied from £99 to £143 per annum. A place like this hospital was entitled to support because of its humanitarian work, and if each person over 15 years of age in Edinburgh would subscribe 6d. per annum this would yield a revenue of £7,866, which would amply meet the deficit on the ordinary income. Baillie Dr. Nasmyth, in moving a vote of thanks to the medical officers, said that the two hospitals provided one-third of the 602 beds available in Scotland for incurable cases.

## Ireland.

#### THE PROBLEM OF THE CRIPPLED CHILD.

THE annual report of St. Mary's Open-Air Hospital, under the care of the Sisters of Charity, has been published. The report states that the Cappagh Hospital is the nucleus for any national campaign which aims at the prevention and cure of diseases leading to deformity in children. Its site is ideal, the building is of the most modern pattern for the purpose, and its therapeutic equipment, including an artificial-sun lamp for use in the sunless days of winter, is thoroughly up to date. The education of the children who are confined to bed for long periods in the hospital is carried out under open-air conditions by specially trained teachers under the approval and supervision of the National Board of Education. The nursing is not excelled in any institution at home or abroad, and the members of the nursing staff have not hesitated to visit and work in similar hospitals abroad in order to compare and improve their methods. Here, therefore, it is argued, is a hospital ready to hand to act as the central hospital of a scheme, which cannot now be long delayed, to deal effectively and systematically with the problem of the cripple in Ireland. The Government is making an effort to increase the efficiency of public health work in this country. Prospective county medical officers of health are undergoing special training abroad. There is a prospect of the badly needed medical inspection of schools materializing. All this must lead to the detection of many cases of tuberculous disease of the bones and joints, of infantile paralysis, rickets, and other deforming conditions, which, in their early stages require skilled orthopaedic treatment in the open-air hospital. Now is the time to provide adequate accommodation for such cases if these public health measures are to provide any practical results, and not merely statistics. But the accommodation requires immediate extension, apart altogether from the cases the new public health measures may bring for treatment. The eighty beds are constantly full. The Sisters at Cappagh believed that if the people of Ireland knew the sufferings of the doomed patients who could not be admitted, accommodation would be provided. They attempted to tell of this need, they embarked on the erection of a new institution, adjoining the present one, but they have not succeeded so far in providing additional accommodation. Two years ago the erection of the new hospital was commenced. Everything went well for a time; the foundations were laid, the walls were rising, but lack of finance and want of response to many appeals caused an inevitable closing down of building operations. To-day a building capable of housing 120 additional cases stands roofless—it has walls, it is true—and the crippled children of Ireland are left to their fate.

## Correspondence.

### SURGERY IN GENERAL PRACTICE.

SIR,—The President of the Royal Society of Medicine has adopted a singular method of supporting the plea, so eloquently voiced by Sir Berkeley Moynihan, that the profession should seek to gain a closer understanding with the lay public. Had Sir James Berry elected to utter his diatribe in the privacy of a meeting of the Section of Surgery of his society there would be no possible cause for complaint. The whole question might make an excellent subject for debate, but to choose an occasion when he must have known that such a pronouncement would be eagerly snapped up by the sensation-mongers of the lay press was surely to show scant courtesy to the humbler members of the profession who had no chance to speak in defence of themselves.

That the war is responsible for what we might call the "democratization of surgery" I do not wholly agree. I held resident surgical posts at my own school in the years preceding the war, and it used to be said then by the younger surgeons that the field of their activities would be considerably circumscribed, as the well educated general practitioner would be capable of doing much of his own operative work. As house-surgeons we used to be given the opportunity of doing a considerable amount of major operating, with the encouragement of our chiefs. Why, with the added advantage of a riper experience to assist us, we should be abused for doing the same thing in our practices passes the understanding of the average general practitioner. I agree with Sir James Berry that operating should only be undertaken by men who have had a thoroughly good grounding—but it is only such men who are likely to accept such a responsibility. To exclude all those who cannot make the practice of pure surgery their life-work displays an extraordinary ignorance of things as they are outside all but the biggest towns. Take the case of an industrial town with a population of 50,000: there is any amount of surgical work to be done, but I can state positively from experience that under the present conditions such a town cannot support a pure surgeon, as nine-tenths of the work has to be performed gratuitously. In the smaller towns situated at a distance from the big centres many lives can be, and are, saved daily by men tackling acute cases on the spot. Would Sir James prefer that these cases should run all the risks of delay, while waiting for a surgical specialist to come from a distance, than that a competent general practitioner should intervene? Personally, I do not think that there is nearly so much chance of the general practitioner surgeon over-reaching himself as there is of the half-baked specialist. Though Sir James Berry may not know it, the general practitioner has to work under a fiercer searchlight than that which beats upon the consultant: he cannot make a mess of a case, and then depart back to the Olympian heights of Harley Street or its local equivalent.

The consultant is not liable to meet that mastoid with facial paralysis every time he walks abroad. The general practitioner is in daily contact with the friends and relations as well as the patient himself, and is constantly brought face to face with them afterwards, so is it likely that he is going to take the slightest risk which he does not conscientiously feel able quite adequately to meet? Personally I do not mind confessing that I would rather have fifty acute abdomens to cope with than one fractured femur (that is about the ratio one meets with these cases in an ordinary mixed type of practice), and I would sooner invite a specialist to undertake the whole treatment of such a fracture than I would a case of acute appendicitis. I rather doubt whether most consultants would appreciate that compliment. The enormous and constantly increasing scope of surgery makes it inevitable that the art of operating must be extended over an ever-widening field; it behoves all who have the best interests of surgery at heart to seek to turn out more perfect technicians in greater numbers, rather than, by hinting at mysteries where none exist, to attempt to restrict practice to the fortunate few. —I am, etc.,

Bradington, Yorks, Nov. 25th.

C. J. GORDON TAYLOR.

SIR,—Sir James Berry's remarks were a great testimonial to the really excellent surgical work performed by general practitioners in provincial hospitals. Given a well equipped, well organized operating theatre, with a well trained nursing staff, then it is only a matter of practice before a quite efficient general surgeon is produced. The appointment of assistant surgeons was a most beneficent reform in our provincial hospitals. One of the most glaring defects of our hospital system is the lack of co-operation between hospitals of different sizes. The teaching hospitals should be linked up with the larger non-teaching hospitals, and these with the smaller. Surgeons from the teaching hospitals ought to be on the active working staffs of large non-teaching hospitals, and surgeons from these on the staffs of smaller and cottage hospitals.

Before closing let me plead that more attention and care should be given to the medical cases in the non-teaching provincial hospitals.—I am, etc.,

Southend-on-Sea, Nov. 25th.

FRED. REES, M.D.

SIR,—May I, as a general practitioner in a rather remote district, and who does not undertake major surgery, be allowed to add to the admirable letters on this subject in your issue of November 27th?

Away from all but the largest cities, the ordinary general practitioner recognizes, and accepts, the fact that his major surgery is, and in most cases necessarily must be, done by others whose facilities for surgical work, by reason of their appointment to neighbouring hospitals of greater or less magnitude, are greater than his own, but whose daily bread is also obtained by general practice.

In nearly every case these same general practitioner surgeons have won his confidence both ethically and surgically, and their generosity in the matter of fees is, as every country practitioner will gratefully acknowledge, indisputable, and better known to himself perhaps than to his patients. I have seen an acute abdominal operation most skilfully performed in the desert by a general practitioner, and am myself indebted for my present existence to an operation in a military hospital by a general practitioner surgeon. After thirty years in ordinary general practice I shall continue, slightly altering Sir James Berry's "cryptic words," to do my best to discover those among my patients who "want an operation" and myself "take care who does it." The pure specialist's fees in these altered times are beyond the power of the vast majority of one's patients to disburse; and, perhaps mistakenly, some of us have gathered the idea that thoughts and inclinations sometimes lean too strongly to removal of some favourite anatomical part whatever the primary condition, and the patient may get (or lose) even more than he pays for.

Competent surgeons are born as well as made, and while training and experience are essential in surgical operating as in all skilled crafts, only the few deserve the true confidence of the many and less gifted, and this is at least as frequently given to the surgically inclined general practitioner of proved merit as to the pure specialist surgeon whose early finances have enabled him to wait those years required to catch the public eye and get a bit of his own back.—I am, etc.,

November 25th.

ANOTHER GENERAL PRACTITIONER.

SIR,—I have always maintained that a general practitioner should not attempt major surgery. He should do unto his patients as he would be done unto, and should ask himself one question, "Would he call in a general practitioner to perform an abdominal operation on himself or a member of his family?"

Surgery is an art, and requires great practice, ability, and dexterity. It is absurd to say that a busy general practitioner can be as efficient as a surgeon, who gives all his time to his art and who has undergone a long apprenticeship. A general practitioner may be quite capable of removing an appendix, but is he certain that his diagnosis is correct, and is he prepared to deal with anything he may find in the abdomen?

As regards fees, I have no difficulty in getting my major surgical work done gratis for those who cannot afford to

pay, and at fees, for people in a better position, that they have no difficulty in meeting.

If surgeons are not encouraged, surgery in this country will degenerate, as it will not be worth a man's while to go through the arduous toil and incur the expense of acquiring surgical skill.—I am, etc.

November 28th.

G. P.

### THE PROPHYLAXIS OF POLIOMYELITIS.

SIR,—In view of the prevalence of poliomyelitis at the present time, it seems advisable to draw attention to the important observations of Flexner and Clark published in 1911 on the effects of hexamine (urotropine) in preventing the disease in monkeys.

"When a large dose is administered by mouth, its presence can be demonstrated in the cerebro-spinal fluid soon afterwards. We have ascertained that when the virus of poliomyelitis is injected intracerebrally in monkeys, in which the hexamine is already present in the fluid, and the drug is then administered by mouth daily thereafter, in a proportion of animals so treated . . . the incubation period of the disease is prolonged from six to eight to twenty-four days, and the onset of paralysis is entirely prevented."

Any attempts to prevent the disease in contacts by similar means have in the past been unlikely to meet with success owing to the very small dose which has to be given on account of the irritation of the bladder and haematuria, which result from the setting free of formalin in acid urine. Our observations in the treatment of cholecystitis during the last four years have shown, however, that as much as 100 grains of hexamine can be safely given three times a day so long as alkalis are administered at the same time in sufficient quantity to keep the urine alkaline, as formalin cannot then be set free and the bladder is not irritated. Dr. F. A. Knott has shown that the alkali does not prevent the urotropine acting on the alkaline bile, and in view of Flexner and Clark's observations it seems unlikely that it would inhibit the action in the cerebro-spinal fluid, which is also always alkaline. I would therefore suggest giving these large doses to all people who have been in contact with the disease until the incubation period of fourteen days has passed, and perhaps for an additional fourteen days because of the possibility that the incubation period would be lengthened by the hexamine as it is in monkeys.

Although Flexner and Clark do not appear to have made any observations as to whether hexamine prevents the full development of the symptom in monkeys when the infection is once established, it has become usual to give the drug during the acute stage of the natural disease. I would suggest that at the first suspicion of the disease being present 100 grains should be given three times a day instead of the usual 10 or 15 grains.

A mixture containing 60 grains each of sodium bicarbonate and potassium citrate in 1 ounce of water is given after breakfast, after tea, and after a glass of milk last thing at night. The hexamine is given at the same time, but in a different mixture, so that the dose can, if necessary, be varied without altering the dose of alkali. It is perhaps safest to begin with 50 grains in 1/2 ounce of water and add a drachm of the solution to each dose every day till the full 100 grains in 1 ounce of water are being given. In the unusual event of bladder irritation occurring the dose of hexamine should be reduced slightly and the dose of alkali further increased.—I am, etc.,

ARTHUR F. HURST.

New Lodge Clinic, Windsor Forest,  
Nov. 24th.

### EPIDEMIC POLIO-ENCEPHALOMYELITIS IN SCHOOLS.

SIR,—This correspondence raises a most interesting epidemiological problem, which may be enunciated in these terms: A few cases of an illness which is known to develop sometimes into an epidemic have occurred within a closed community; is it better to keep that community closed or to disperse its members, (a) from the point of view of the members of the community, (b) from that of the whole population?

In the first place, we must ask whether we have sufficient knowledge of the epidemiology of the particular illness

to be able to say that it is, epidemiologically, *sui generis*, so that analogies drawn from the epidemiological behaviour of other illnesses are worthless. The two best summaries of epidemiological knowledge of poliomyelitis which will be available to all readers are, I think, Batten's paper<sup>1</sup> and Reece's study of the epidemics of 1911 in Cornwall and Devon.<sup>2</sup>

The conclusions we may draw from past experiences are: (1) That, taking as a measure the ratio of cases exposed to risk, poliomyelitis is much less infective than scarlet fever or diphtheria (Batten, p. 206). Such epidemics as that of Trästena in 1905 and Stoke Rivers in 1911 suggest that the intimate admixture of children from different families in a common school is an important factor in increasing infectivity. A corollary is that the considerations suggested by Power's classical report on diphtheria in Pirbright are relevant. If I am right in this contention (I, of course, recognize that it may be swept away by the production of real proof that the epidemiology of poliomyelitis is *sui generis*) then experimental work on the effect of aggregation as compared with segregation in other infections is relevant.

In the third of Professor Topley's Milroy Lectures<sup>3</sup> will be found a summary of experiments on mouse-typhoid. The problem was to determine whether, when an epidemic had begun in a herd of mice, the mortality would be affected by partial segregation. Suppose that from such a community we take 100 individuals and keep them together in a herd, and another 100 individuals whom we divide into ten groups of 10 each, which 100 will experience the heavier mortality? The answer was unequivocal. If the segregation is effected at an early stage of the epidemic, before many deaths have occurred, the ten batches of 10 will suffer much less than the undivided 100. If one delays until the epidemic has gathered strength, segregation will have little effect. As Topley says:

"It is not difficult to suggest a possible mechanism for the effect of dispersal upon the total mortality. Whether the important factors in the production of fatal infection be the size of the first dose of bacteria received, the rapidity with which successive doses follow each other, the relative virulence of the bacteria, or the relative resistance of the receiving host, we have seen that the effectiveness of these factors must be expressed in terms of chance. By dispersing the population at risk we shall redistribute these chances in a random way, and the sphere of action of those mice which are acting as dangerous centres of infection will be limited."

So far, then, as the interests of the members of the herd themselves are concerned, breaking the herd up is clearly the right policy. But it may fairly be contended that the parallel is not a strict one, for the groups of 10 were not mixed with other mice which had not formed part of the original community. May not the dispersed members of the small herd, the school, light up disease in the general community; may not the interests of the small herd be opposed to those of the larger herd, the whole population, of which they are part?

The general teaching of epidemiology that the presence of a sick person or a carrier is only one of the factors of an epidemic is familiar to all educated men. Experimental work of Professor Topley and myself shows that even in diseases of much greater infectivity than poliomyelitis (for example, pasteurella infection) it is not sudden exposure to a large number of non-immunes, but the steady circulation of non-immunes through a community containing infected or carrying individuals, which is a fundamental condition of high epidemicity.<sup>4</sup> It does not appear, therefore, that any increased risk to the greater herd does counterbalance the advantage to the smaller herd which dispersal of the latter involves.

Finally it may be noted that when the survivors of the dispersed herds in Topley's above cited experiments were reassembled (in the case where dispersal took place before the epidemic in the original herd had reached a maximum) the disease broke out again. Hence it is prudent only to reassemble a herd after a considerable interval, and it might be wise not to admit new comers to it for a still longer time.

<sup>1</sup> *Proc. Roy. Soc. Med.*, Epidem. Sect., vol. iv, p. 153.

<sup>2</sup> *Ibid.*, vol. v, p. 59.

<sup>3</sup> *Lancet*, March 27th, 1925.

<sup>4</sup> *Journ. Hyg.*, xxiv, 1925, pp. 45-110.

The continuous study of morbidity in closed communities, such as boarding schools, is of extraordinary interest. A report to the Medical Research Council by Surgeon-Commander Dudley (now at press) illustrates this and also our real need for further information.—I am, etc.,

Loughton, Nov. 27th.

MAJOR GREENWOOD.

#### CANCER RESEARCH.

SIR,—The valuable paper entitled "Some physico-chemical and biochemical aspects of malignant neoplasms" by Professor W. C. M. Lewis (BRITISH MEDICAL JOURNAL, November 20th, p. 920) contains many interesting observations made by foreign scientific men, but gives little or no recognition of the important work of our own countrymen on the subject. For instance, I am surprised to find no reference to the work of Dr. J. A. Shaw-Mackenzie on the biochemical side of the problem, who for many years has shown, among other facts, that tissue lipolysis and utilization of fats is defective in cancer.

In the subheading "Lipolytic (esterase) activity in malignancy" Professor Lewis recalls the observation of Bauer<sup>1</sup> that "every human serum examined contains fat-splitting enzymes which are greatly decreased in carcinoma and advanced phthisis"; and he goes on to emphasize a differentiation between true fat-splitting enzymes and esterases which act on lecithin, as indicated by Bloor.<sup>2</sup> A differentiation between a true fat-splitting enzyme and esterase was dealt with as early as 1910, in the *Journal of Physiology*, by Rosenheim and Shaw-Mackenzie. They were able to confirm previous statements on the lipolytic action of serum—namely, that a true fat-splitting enzyme is not present in serum, "whilst even the action of what might be called a butyrase on the esters of lower fatty acids is a feeble one." They noted, however, that "serum, although not possessing any fat-splitting action by itself, increases in a remarkable way the lipoclastic activity of pancreatic lipase." In these researches it was found that lipase itself in pancreatic extracts and in pancreatic juice is separable into two parts—namely, "co-enzyme" and "inactive lipase" or pro-lipase, neither of which has any fat-splitting action alone but together become active. The importance of this in all its bearing has hardly received the attention it deserves. Serum contains an activating agent different from but analogous to the pancreatic co-enzyme of lipase, and in this way the activator or activators carried by the blood enable the lipases of the tissues to hydrolyse the fats brought to them by the blood stream after digestion. It was pointed out also that cholesterol "in all cases was found to exert an inhibitory action," not only on lipase, but on the accelerating action of serum with its contained activators. It was found also that lecithin is readily split by lipase, as previously shown by Maclean.

In the course of this work variations were observed in the accelerating action on lipase of a variety of substances, organ press juices, the serum of lower animals, and of the serum in certain diseases. In 1913, in a paper given before the International Congress of Medicine, London, Dr. Shaw-Mackenzie pointed out that the power of the serum to increase fat-splitting is decreased in cancer, in the acute stages also of tuberculosis, and in other bacterial infections. The experiments were repeated. The results fully confirmed his earlier ones, and were detailed by him in a paper published in the *Journal of Physiology* in 1915.

This decreased power of the serum frequently enables a positive diagnosis of cancer to be made in doubtful cases, or the presence of cancer to be excluded. It formed the basis also of further blood tests, dependent in part on the increased cholesterol content in the serum of cancer patients.

The main outcome of these researches on lipase since 1911<sup>3</sup> and onwards has been to show that natural and induced tissue lipolysis with the fatty acids or their sodium salts are important factors in the protective processes and resistance of the body in malignant disease.

The bearing of these researches clearly indicates the importance of the chemical and medical side of the problem

of cancer and its treatment, having for its aim the reinforcement of natural physiological defensive processes of the body, and stimulation of tissue lipolytic activity with destructive action on the fats and lipoids of the cancer cell. Perhaps the most striking indication is the application of therapeutic measures in this direction in post-operative cases in the hope that the sum total of recurrences may in some measure be reduced.—I am, etc.,

#### MONGOLIAN DEFECTIVES.

SIR,—According to the brief report of Dr. Clarkson's Henderson Lecture, given on page 1015 of your issue of November 27th, I am supposed to have supported, in *The Mongol in our Midst*,<sup>1</sup> a polyphyletic scheme of human origins that is negatived if the mental characteristics of Mongolian defectives are considered, since, in Dr. Clarkson's opinion, any ancestral branch of the human race that had such characteristics must have died out very soon and left no descendants. This is as it may be; but, in fact, I have never suggested the former existence of any such ancestral branch. An "atavistic" explanation of the occurrence of Mongolian characteristics amongst pure-bred "Europeans" no more calls for belief in the former existence of such a branch as Dr. Clarkson has in mind than does the "recapitulation" explanation of embryological and infantile characters require belief in the former existence of any race of creatures just like a human embryo at any stage of its development. If I point out that the turtle heart of a dead infant with congenital heart disease may be "explained" by the theory that mankind passed through a reptilian stage on its way from the amoeba hither, would my view be "negatived" by the statement that a race of such creatures as the child in question would have died out and left no descendants?

Now the homologies between the Mongolian defective, the racial Mongol, and the orang are indisputable. Sera has described skeletal homologies between the Japanese and the orang; Kurz has shown that the brain of the Chinese child is distinguished from the brain of another child by just those characters which distinguish the brain of the orang from that of another ape; and Gans has shown that the brain of the Mongolian defective is distinguished by just those characters that distinguish the brain of the Chinese child and the orang. It is with such facts as these that I am concerned, rather than with any attempt to "prove" a triple line of descent for mankind. But it is an obvious duty to inquire whether these new facts are compatible with the orthodox monophyletic schemes, now a little blown upon. As a matter of fact, they are not, and it would seem that all good Darwinians, who accept as axiomatic the assumption that homologies prove descent, must either ignore the new facts or be content to accept some one of the polyphyletic schemes, which do at any rate have this in their favour, that they afford a convenient explanation of the otherwise unexplained occurrence, in our midst, of not only defective but even distinguished "mongoloids," some of whom beget children and transmit their peculiarities, or some of them, on more or less Mendelian lines.—I am, etc.,

London, W.1, Nov. 29th.

F. G. CROOKSHANK.

#### CLOTHING AND CATARRHS.

SIR,—Mr. Jordan has mistaken the purport of my letter. The question on which I ventured to address you on November 15th was not as to whether my views on the respiratory function of the skin were correct, but as to whether Mr. Jordan was justified in charging me with insincerity in expressing them. That is a purely personal question on which, having made my protest, I do not propose to trouble you further.

Let me add that even if I were inclined to engage in a public discussion on the subject of cutaneous respiration, I should decline to do so with one who includes among his controversial methods the puerile expedient of assuming that his opponent's only authorities were derived from intuitions, and the wholly indefensible one of attributing unworthy motives to those from whom he differs. In the

<sup>3</sup> *Proceedings of the Physiological Society*.

<sup>1</sup> *The Mongol in our Midst*, second edition, London, 1925. Pri

atmosphere created by such amenities a reasonable exchange of views on any subject is impossible.

It is not my custom to answer questions addressed to me in the tone adopted by Dr. Gallagher, but if he will consult Luciani's *Human Physiology* (Macmillan, 1913), vol. ii, p. 495, he may possibly be led to conclude that the problem of cutaneous respiration is not yet ripe for the kind of dogmatic statement which he seems to affect.—I am, etc.,

London, N.W.1, Nov. 30th.

LEONARD WILLIAMS.

### "RISING OF THE LIGHTS."

SIR,—The quotation from Buchan's *Domestic Medicine* is very interesting, as it gives an explanation of this mysterious name, but I think that if it refers to deaths from throat disease it would apply to all forms of inflammatory trouble, not diphtheria only. These would include acute septic conditions like angina Ludovici. Now there are a great many references to "putrid sore throat," which in some but not in all cases may have been diphtherial. Our ancestors could distinguish different kinds of such inflammations. Huxham's, of course, is the classical instance of a clear definition. The wonder is that there were not more returns under this head, seeing that in London alone, as late as 1850, not one water supply was uncontaminated, as may be gathered from Hassall's pamphlet of that date, with excellent coloured illustrations of the poisonous material found in every one of the then sources of the various water companies. Sewer drainage had added to the pollution of the Thames in the nineteenth century.—I am, etc.,

Appledore, Kent, Nov. 17th.

F. WILLIAM COCK.

SIR,—I have come across this expression both in the East and West of England, with varying meanings. In Cornwall it is used of flatulent dyspepsia with frequent eructations. In the course of my collection of material for a book on folk-medicine in Eastern England I have received the following items:

From a pharmacist at Peterborough: "In 1890 a woman called at my pharmacy from Thorney Fen for something for her husband who was really suffering from liver and stomach troubles. She complained he had always something in his throat; on being asked if he had taken any medicine, imagine my feelings when the reply came, 'He had swallowed some shot to keep his lights from rising.' On making inquiry afterwards I found this to be a common practice."

A doctor in North-East Suffolk wrote in 1925: "An old lady of my acquaintance used to swallow small shot in handfuls 'to keep her heart and lights down.' She never suffered from lead poisoning, but died of an intracapsular fracture of the hip, possibly due to increasing weight."

Varden, quoting *Chambers's Book of Days* (about a hundred years ago), tells of a good old soul who was troubled by "rising of the lights" and who "took a dose of shot and that kept 'em down." I have heard of another old lady who, troubled by the same complaint, used to "shove 'em (the lights) down with a tablespoon."

With regard to the application of remedies to the soles of the feet, I have come across a number of modern instances, most of them rather unpleasant.

For pneumonia "wrap the patient's feet in calf's liver hot from the slaughter and give a teaspoonful of goose grease at frequent intervals" (a gipsy remedy from Blythburgh, Suffolk).

For typhoid fever "the spleen of a bullock, raw, applied to the soles of the patient's feet as a cure" (from Great Yarmouth). "The milt or spleen of a cow or the skirt of a sheep, applied to the feet, is supposed to draw the fever from the head and thus bring about a speedy cure" (*East Anglian Handbook*, 1835).

For whooping-cough "peel a garlic and wear it in the right shoe" (Welby, Suffolk).

I have met with sulphur placed in the boots as a remedy for rheumatism in Norfolk, and for psoriasis in Cornwall. In the latter case it was prescribed by a doctor, and, combined with a thorough dredging of sulphur all over the body, effected a cure in a case of "English leprosy."

With such a widespread use of the term "rising of the lights" nowadays, it is very unlikely that its meaning was ever confined to any specific disease, unless by a purely local custom. The class of people who would use such a term are far too conservative to have allowed a hundred years or two to have made any difference in their nomenclature. "Lights" to the ordinary person means an animal's lungs, but if the local butcher is asked for a

pennyworth of "lights" for the dog, probably some spleen and possibly pancreas will be included in the parcel along with the lung and trachea. I think "rising of the lights" probably meant any disease that caused a sensation of something coming up, or an actual appearance of something, whether from lungs or stomach.—I am, etc.,

Norwich, Nov. 14th.

MARK R. TAYLOR.

SIR,—As the writer of the article in your *Nova et Vetera* column of October 9th on the Bills of Mortality, I have been much interested in the correspondence on "rising of the lights."

As a student I was told that this term was a synonym for emphysema, but it appears from your correspondents' letters and from a discussion of the question in *Notes and Queries* (8th series, vol. vi, pp. 308, 415, and 516) in 1894 that it has been used to denote a sense of fullness in the throat accompanied by oppressed breathing. John Graunt, in his "Observations," remarks on the relation in the Bills of Mortality between "rising of the lights" and "mother," and shrewdly suggests that the two were names for the same thing, so that "rising of the lights" must be simply globus hystericus. It is difficult to accept this suggestion in this case, seeing that hysteria is not a very fatal disease, yet in 1629 forty-four deaths were attributed to "rising of the lights," and only one to "mother."

Another contributor to *Notes and Queries* quotes MacCulloch as saying that Sydenham solved the question in treating of this disease under hysteria. Another contributor, J. Astley, writing from Coventry, stated:

"In this district a sense of fullness in the throat, accompanied by oppressed breathing, arising from disordered stomach, is attributed to a 'rising of the lights,' i.e. lungs, and the common remedy is to take either some small gun-shots, or a globule of mercury (about a quarter of an ounce), in order by their weight to keep the lungs down! I cannot report any beneficial effect of the medicine."

This remedy of small shot or mercury, meant to force the rising lungs to descend, seems to have been very general.

The identification with croup is strengthened by the fact that in the Bills of Mortality for 1796 rising of the lights disappears as a cause of disease and croup alone remains.

Finally, the term would appear to be popular in America, for the author of *Mrs. Wiggs of the Cabbage Patch* puts it into the mouth of one of her characters as applied to a horse! (*Notes and Queries*, 10th series, vol. iv, p. 66).—I am, etc.,

November 23th.

E. M. L.

\* \* We are afraid that these lights must now be quenched.

### APPENDICITIS AND VEGETARIANISM.

SIR,—The statistics quoted by Mr. Robert H. Perks in your issue of October 2nd (p. 616), on the infrequency of appendicitis among the natives of Northern India, are rendered more striking when it is remembered that the majority of the inhabitants of the Punjab are Moslems or Sikhs, and that both communities are extensive meat eaters. They also, unlike the Hindu community, allow themselves to suffer severely from constipation. It is therefore not quite clear to what they owe their immunity from the disease.

Captain Williamson's statement in your issue of October 16th, that he has never removed an Oriental appendix, is surprising and contrary to my experience in my very restricted surgical practice in India. I have performed eight operations for appendicitis during the past two years in India, and of these three were on Indians. The pathological conditions found in each case were: (1) Gangrenous appendicitis with peritonitis, (2) perforated appendix with abscess, (3) catarrhal appendicitis.

In two other instances when operating on Indians for tuberculous peritonitis and pancreatic cyst respectively, the appendixes were observed to be the seat of catarrhal inflammation.—I am, etc.,

J. DESMOND O'NEILL, M.B., B.Ch.,

Jubbulpore, India, Nov. 7th.

*Medico-Legal.*

## THE PRESTON CRIMINAL ABORTION CASE.

## BOTH PRACTITIONERS ACQUITTED.

THE Grand Jury at the Manchester Assizes having thrown out the bills on charges of murder against Dr. Arthur Stuart Holden of Preston, and Dr. Frederick Langton Webster of Bamber Bridge, but returned true bills on charges of manslaughter and felony, the two accused doctors were arraigned on these charges arising out of the death of Nora Elizabeth Marmion, aged 24, at the Assizes on November 29th, before Mr. Justice Branson. The trial lasted two days, and resulted in the petty jury finding a verdict of not guilty, the Judge remarking: "I think it is right to say I entirely agree with your verdict."

Although the charges against Mrs. Constance Mary Holden, Mrs. Helen Blackburne (the deceased woman's sister), and her husband, Major William Edward Blackburne, bank manager, of being accessories to the murder were withdrawn in the course of the magisterial hearing, their names appeared on the assize calendar, as they had been committed on coroner's warrants. No evidence being offered by the prosecution, the jury on the direction of the judge returned a formal verdict of "Not guilty," and these accused were discharged.

The previous proceedings in the coroner's court and at the magisterial hearing were reported in the *BRITISH MEDICAL JOURNAL* of November 6th (p. 860) and of November 13th (p. 909).

Mr. T. Eastham, K.C., and Mr. Neville Laski appeared for the Crown; Mr. J. E. Singleton, K.C., and Mr. Lustgarten for Dr. Holden; Mr. J. C. Jackson, K.C., and Mr. Lustgarten for Dr. Webster; Mr. N. B. Goldie for Mrs. Blackburne; Mr. G. G. Blackledge for Major Blackburne; and Mr. Lustgarten for Mrs. Holden.

Both the accused medical practitioners pleaded not guilty.

*Case for Prosecution.*

Mr. Eastham, in opening the case for the Crown, remarked that up to the matters complained of both doctors bore excellent characters and reputations. Miss Marmion was a single woman of no occupation, and lived with her father. Counsel referred to her friendship with a Mr. French, to a visit she paid to her sister Mrs. Blackburne, and then to a visit to the house of Dr. Holden in October last. That visit, he suggested, was paid with a view to consulting Dr. Holden about her condition, and, as a result, counsel proceeded to suggest, Dr. Holden and his wife, on October 7th, called at Major Blackburne's flat with a motor car and took Miss Marmion to Bamber Bridge, saying they were going to play bridge. They went to Dr. Webster's house, and the prosecution's allegation was that an illegal operation was performed there either by one or both of the accused, and that Miss Marmion died from shock during the operation. At 2 a.m. on October 8th both doctors went to the police station at Bamber Bridge and saw Inspector Blenkinsop. Dr. Webster, as it happened, was the inspector's family doctor, and had attended the inspector's son. Dr. Webster said to Inspector Blenkinsop: "This is Dr. Holden. He has had an operation on a lady at my house to-night. She has died under the anaesthetic." Dr. Holden said: "I have let Dr. Webster in. She was my patient, and Major Blackburne's sister-in-law." Dr. Webster then added: "Yes, she has died at my house; she was his case." Later, at his own house, Dr. Webster said to the inspector: "I am innocent of this charge. They came to my house to play bridge." Counsel said Inspector Blenkinsop had allowed the two doctors to leave the police station without first informing his superior. He had completed twenty-seven years' service in the force, and at the time had been through a serious illness and an operation. On November 4th last he attempted to take his own life by prussic acid, but fortunately the attempt was unsuccessful.

Evidence was then called for the prosecution.

After Mr. Peter Marmion (the deceased woman's father) and Mr. Alexander French had given evidence, counsel intimated that he did not propose to offer any evidence in the cases of the three persons committed on charges of being accessories, but he wished to call Major Blackburne. Mr. Lustgarten objected, stating that although Major Blackburne was not under arrest at the time he gave evidence at the inquest, he was now under arrest, and was a prisoner on bail. The judge said he thought that calling Major Blackburne placed him in a difficult position. Major Blackburne was not called into the witness-box.

*The Doctors' Statements to the Police.*

Inspector Blenkinsop gave evidence in support of counsel's opening statement.

Mr. Singleton (cross-examining): Did Dr. Webster say to you that the lady was really Dr. Holden's patient, but as death had occurred in his house he thought it was his duty to report it to the police?—No; he did not say that.

Was the coroner mentioned?—No.

Did Dr. Holden say it was an examination he was making of her under an anaesthetic?—No; he did not.

Did he say she had come round from that anaesthetic but went into a fit and died?—No.

Did he say, "I cannot understand why she died"?—No.

Personal friend then a patient?—No.

If your evidence is correct I assume you took it there had been prior to the doctors coming to you a criminal offence committed by them?—Yes.

When was it you attempted to commit suicide?—November 4th.

In reply to Mr. Jackson, who asked why he did not arrest them, the witness said that one doctor said the woman had died from an

anaesthetic, and the other gave another reason; he wanted to see the body. The question was repeated, and the witness then replied: "I admit I made a mistake there." He wrote the particulars of Dr. Webster's statement on a slate, but the writing was subsequently rubbed out; he did not know how. He did not know the statement was going to be challenged until the inquest. In re-examination, the inspector said he attempted to take his own life because he had been reduced by his superior for not detaining the two doctors.

Medical evidence was then given.

*Medical Evidence for the Prosecution.*

Dr. W. A. Simpson, acting police surgeon at Bamber Bridge, said his *post-mortem* examination caused him to form the opinion that death was due to asphyxia owing to the action of an anaesthetic upon a fatty heart. Cross-examined, he said he performed the examination about thirty-six hours after death. He smelt no trace of anaesthetic, but vomiting or attempts at artificial respiration might take away the smell.

Dr. K. M. Duncan, senior police surgeon for the county of Lancaster, who was present at the necropsy, said he did not altogether agree with Dr. Simpson's opinion as to the cause of death. In his own opinion, death was more likely to have been due to shock than to asphyxia caused by an anaesthetic. He detected no trace of an anaesthetic, but he admitted that his sense of smell was very poor. Cross-examined, he agreed that it was difficult with any certainty to give the cause of death. Shock from asphyxia might be the cause of death.

Sir Bernard Spilsbury, honorary pathologist to the Home Office, described his examination of the heart and uterus. He detected no smell of chloroform, ether, or any other anaesthetic, though it was usually to be detected where it had been used. There was nothing in the condition of the heart to account for death. He came to the conclusion that an instrument had been used, and that an ovum had been removed after death. He was of opinion that the deceased woman was about two months pregnant, and he proceeded to give his reasons for that opinion. He attributed her death to shock due to the passage of an instrument. The uterus was quite healthy, and there was nothing in its condition—no disease—to necessitate the passing of an instrument.

Cross-examined by Mr. Singleton, Sir Bernard Spilsbury said he had had experience of thirteen cases of death from shock following immediately after the passage of an instrument. They were all cases in which he had been called in by police authorities. He agreed that before he examined the organs submitted to him he had received certain police reports, and that he made his examination with the knowledge that it had been suggested that an illegal operation had been performed, and no evidence in support of that had been disclosed by the *post-mortem* examination.

Mr. Singleton drew attention to the witness's description of the mark which he attributed to the passage of an instrument, and pointed out that not one of the three well known professional men who had made an examination of the body had been able to see any trace of such a mark. Sir Bernard Spilsbury replied that he could well believe it, but it had not occurred to him that what he found was very probably not the mark of any instrument.

*Case for the Accused Practitioners.*

Mr. Singleton said the case for the prosecution rested entirely upon the evidence of Sir Bernard Spilsbury, and he submitted that it had not been proved either that death resulted in the way that Sir Bernard Spilsbury had suggested or that an illegal operation had been performed. The medical profession was a body rightly proud of its own reputation, and would be no party to illegal operations. The accused all their days would have cause to be grateful for the help of eminent members of their profession who had come forward to give evidence to help the defence in order to show that what Sir Bernard Spilsbury had put forward as his theory would not hold water. These were two men of unblemished reputation. Not a word could be said against their characters, and yet it was on the theory of Sir Bernard Spilsbury alone that the jury were asked to convict them.

*Evidence for the Defence.*

Dr. Holden, in evidence, said he had a large practice and there was not the slightest need for him to stoop to any illegal practices. He knew Dr. Webster as a schoolboy, but had lost sight of him until after the war. He had known Miss Marmion about two years, having met her with the Blackburnes. She was not a patient of his before October of this year. On October 6th she made a statement to him of an occurrence at Waterloo Park, and told him her sister did not know of the matter. He said she must go home and tell her sister and brother-in-law, and he later made an examination at the Blackburnes' house, but found nothing to suggest that the girl was pregnant. The following night he telephoned to Dr. Webster and arranged for a game of bridge. There was no thought of any operation. At Dr. Webster's house Miss Marmion complained of pains in her back and right side; it was her own request that she should be examined. He and Dr. Webster both advised her to go into a nursing home. She objected to that because she said it would upset her sister. She wished to be examined there, and said if they found anything that would warrant her removal to a nursing home she would consent to go. She then asked whether she could have a slight anaesthetic as she was in pain. That suited him because he had already made an examination not under an anaesthetic. It was quite usual to give an anaesthetic for a fuller examination of this nature. Dr. Webster tested the girl's heart and made an examination usual before anaesthesia. The anaesthetic used was A.C.E. mixture. Witness then made the examination in the presence of his wife and Dr. Webster. As a result both he and Dr. Webster were perfectly satisfied that Miss Marmion was pregnant.

Mr. Singleton: Was any illegal operation performed at any time?—None whatever.

Continuing, Dr. Holden said when the effects of the anaesthetic began to pass, his wife called to him: "I don't know what is the matter with Norah. She has gone pale." If then noticed that Miss Marmion's pupils had begun to dilate: they soon became very much dilated. Her pulse was quick, but small. Presently, her face began to go blue and she raised her forearms, clenched her fists and teeth, and went into a convulsion. Dr. Webster exclaimed: "Good heavens, she is having a fit." He at once looked for restoratives and then began artificial respiration whilst Dr. Webster massaged the heart and his wife raised the girl's legs. A hypodermic injection of strychnine was given, and even the old method of mouth-to-mouth breathing to inflate her lungs. They were at work for two hours, and Dr. Webster said at last: "It is no use going on any longer: she's dead." He and Dr. Webster then paid a visit to the police station. Dr. Webster said: "This is Dr. Holden. A lady has died at my house to-night following the administration of an anaesthetic." The witness gave the inspector particulars which were written down on a slate. Then the inspector said: "I cannot do any more about this until the morning. I think that will be all; good-night." As an after-thought the inspector said: "By the way, what was the complaint the lady was suffering from?" The witness said it was a case of an examination under an anaesthetic in which he found that the lady was not pregnant. He did not say a word about criminal operation. Miss Marmion had told him she was going to be married to the boy French in the spring.

Mr. Eastham (cross-examining): If you had nothing to conceal, why did not you give your explanation before the coroner?—Because I was advised not to. You must remember that when the time came for me to do so, Sir Bernard Spilsbury had already given his evidence. He had made these extraordinary statements and we had not had any pathologist to refute them.

Do you say no preparation was made for giving an anaesthetic?—No preparations that I know of, but I understood the girl had had no food for about four hours.

Was it not a very odd time and a very odd place to give an anaesthetic to a woman?—No time is an odd time and no place an odd one if it is necessary.

Asked what he meant by his statement to Inspector Blenkinsop, "I have let Dr. Webster in," Dr. Holden said he had been misunderstood. He meant there would be a *post-mortem* examination at Dr. Webster's, and that would let Dr. Webster in for a mess in his house.

Dr. Thomas Watts Eden, consulting obstetric physician to Charing Cross Hospital, said he had great difficulty in accepting Sir Bernard Spilsbury's evidence as to the cause of death, because the doctor who made the *post-mortem* examination came to another opinion. In his own opinion, asphyxiation would be a reasonable explanation of death, coupled with the condition of the heart. He did not think there was any conclusive evidence of an instrument having been used, or that an operation had been performed. He did not agree that there was evidence of any operation being performed even after death.

Dr. Sidney Rawson Wilson, lecturer in anaesthetics and applied physiology in the University of Manchester, said he was of opinion that the condition revealed *post mortem* was consistent with death from syncope, and with the administration of a light anaesthetic. If there was some fatty degeneration of the heart the patient would be very likely to collapse. The witness had himself had many cases in which he had been unable to detect the smell of anaesthetic, except when very deep and prolonged. He had that morning performed two experiments showing that after anaesthetic for an hour and a half it was smell of it.

Shaw, gynaecological surgeon to the Manchester Royal Infirmary, said he did not think the evidence of the *post-mortem* examination conclusive, either as showing death from shock or death from an anaesthetic. It would have been impossible for the contents of the uterus to have been removed in the way suggested. He could see no evidence conclusive of the use of an instrument.

Dr. Daniel Douglas, lecturer in obstetrics and gynaecology in the University of Manchester, said that the evidence in favour of pregnancy was not conclusive, and he found no evidence of an instrument having been used for the purpose of an operation.

Dr. Webster, in evidence, said he was qualified in 1915, and was severely wounded on the Somme. Since 1922 he had been in practice at Bamber Bridge. He first met Miss Marmion on September 15th this year. On the night when Miss Marmion died she arrived at his house for cards with Dr. and Mrs. Holden. She looked ill, and was shivering, and, after a time, Dr. Holden asked permission to take her to the consulting-room. She was sitting on a chair, complaining of severe pains in the right side and back. Dr. Holden suggested that he should take her home, or that she should go to an infirmary or nursing home. Miss Marmion disagreed, and asked if she could be examined there, and she herself suggested an anaesthetic. Before administering the anaesthetic he took every precaution. Miss Marmion had told him she had had two previous anaesthetics. He denied that he had performed any such operation upon her as the one alleged, and repudiated the suggestion that Dr. Holden performed an operation whilst he (the witness) was occupied with administering an anaesthetic. Regarding the interview at the police station, the inspector seemed very disturbed at seeing him. He did not hear Dr. Holden's reply when the inspector asked what complaint the lady had suffered from. The only words he did hear were "pregnant," and the sentence, "I have let Dr. Webster in." Cross-examined by Mr. Eastham, he denied that he heard Dr. Holden say the girl was pregnant.

Mr. Eastham: Why did you go to see a solicitor if there was no suggestion of abortion?—Because I was rung up by a solicitor who advised me to go to see him.

Mr. Jackson, addressing the jury, said the foundation of the case was the evidence of Inspector Blenkinsop. Sir Bernard Spilsbury came to the case knowing that these men were said to have confessed to criminal abortion. Starting with this knowledge, Sir Bernard, as the Home Office pathologist, proceeded to look for every trifle that bore out the story. As to the police inspector, the man who in trouble took prussic acid, was he a man upon whose mind and recollection they could rely?

#### Summing-up and Verdict.

Mr. Justice Branson, in his summing-up, said they had heard that both of the accused doctors had hitherto borne irreproachable characters, and that was a matter that should be taken into account. The importance of the case could not be exaggerated. If they were convicted the accused would not only get severe punishment, but they would be ruined in their profession.

The jury retired, but within a quarter of an hour returned, and announced a verdict of "Not guilty." The announcement was the signal for an outburst of cheering, and the court officials had some difficulty in obtaining silence.

On other counts in the indictments against the two doctors no evidence was offered, and the jury returned a formal verdict of "Not guilty."

Mr. Laski said the prosecution thought it highly desirable that he should say that Major Blackburne went out of the court without a stain on his character. The future of Major and Mrs. Blackburne and Mrs. Holden being at stake, it was very important that the public should know that all charges against them had been withdrawn.

The defence of both Dr. Holden and Dr. Webster was undertaken by the London and Counties Medical Protection Society, Ltd.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

THE House of Commons has this week made good progress with minor bills, including the Births and Deaths Registration Bill and the Mental Deficiency Bill. The date of enforcement for the former bill has been altered, and the varying definitions of mental deficiency in the latter may be correlated at a later stage. The Government put down the concluding stages of the Smoke Abatement Bill for November 30th, but had to postpone them. The session is expected to end on December 17th, by which time the bills mentioned above and the London University Bill will probably have passed into law. The Government's proposal to reduce the housing subsidies after next September was down for discussion in the Commons on December 2nd, and the coal dispute will probably be reviewed in a debate on December 8th.

The Parliamentary Medical Committee met at the House of Commons on November 24th, Dr. Fremantle presiding, and received a deputation, headed by Colonel Peck and Captain Hill, which represented ex-service pharmacists. The Director-General of the Army Medical Service also attended. The deputation explained that they desired the appointment to the army of two army pharmacist officers of commissioned rank—one at Aldershot and one on the staff of the R.A.M.C. The purpose of these appointments would be for training dispensers and advising on contracts and on mobilization schemes. The Parliamentary Medical Committee promised to consider the proposals, but it was pointed out that the suggestions made would establish a new branch of the Service likely to involve expense. Questions to the Director-General showed that army dispensing is done, for the most part, with drugs already compounded, and that contracts for drugs and dressings are made on a large scale with better economic results than by the system of making up which the deputation suggested. The Director-General said, however, that he would make personal inquiries at some of the big hospitals where drugs were prepared on similar systems to that which the deputation of pharmacists suggested. After the deputation withdrew the Medical Committee asked the Director-General some questions about such service matters as amalgamations of hospitals, since further amalgamations are now being considered separately in each service centre. The closing of an army hospital at Chatham was mentioned, as also a proposal now under consideration to concentrate military hospitals from all round the Kentish coast at Gillingham. The difficulty, it was thought, would be to obtain economy while ensuring efficiency in sudden pressure. Sir Richard Luce asked what further economies, if any, were contemplated in the Territorial Army Medical Service, and what was the chance of restoring the three skeleton field ambulances previously provided per division. The Committee then went over the Rural Housing, Smoke Abatement, Coroners, and Births and Deaths Registration Bills as they then stood.

#### Births and Deaths Registration Bill.

The Births and Deaths Registration Bill was considered on the Report stage in the House of Commons on November 29th.

Mr. Basil Peto moved the following new clause: "The death of any person shall not be registered unless and until there has been

delivered to the registrar of the district in which such death has occurred a certificate signed by a medical practitioner of the fact of death and of the cause of death, as respectively in this Act defined, and such certificate shall be given only after the medical practitioner has seen the body." The bill, he said, provided no machinery for the inspection of a body after death. There could be no disposal of the body without a registrar's certificate, but that certificate only stated that that official had registered the death. He asked for an assurance that the Ministry of Health possessed powers to put an end to the present unsatisfactory state of affairs, by which a very large number of people supposed to be dead, but were not really dead, were in danger of immediate burial. The fact of death should be certified by a medical man who had seen the body.

Mr. Groves, in seconding the new clause, expressed the same opinion. According to the Registrar-General, only 40 per cent. of the people buried in this country were certified on medical evidence to be actually dead. The whole matter was one of expense. The Government could not find the money to do what was required, and medical men would not do it without payment. After all, the panel doctor was responsible for his panel patient until life was extinct, and it ought to be his duty to certify that life was actually extinct after seeing the body. A similar rule should obtain in Poor Law institutions and hospitals. The new clause gave the Government an opportunity to make the necessary representations to the General Medical Council seriously to consider the matter, and to see if this long-standing grievance could not be brought to an end.

Dr. Fremantle said that this clause was an alternative to that which he had put down, which was originally a specific clause in the bill with which he was personally associated. In the bills he had introduced in previous years on this subject his aim had been to meet the particular objections put forward by Mr. Peto. The stage which Mr. Peto and his friends had reached was one he (Dr. Fremantle) had passed through, with many others. This matter was not merely one of expense; the real question was that it was impracticable from the point of view of the doctor's time. That argument really met the statement that only 40 per cent. of deaths were certified after a personal view of the body by the doctor. If the doctor was visiting a patient regularly, and the patient was gradually going downhill, the doctor could not watch and be there, and was of no use if he were there, every minute right up to the very last. The doctor saw the end coming, and he naturally discreetly retired. He would call in the course of his round, and he would retire when there could be no question about the end. It was safe to conclude that in practically every one of the 60 per cent. of deaths certified without actual view of the body the doctor was quite assured in his own mind, when he signed the certificate, that death had supervened and was bound to do so. In ordinary practice the doctor was busy on his round from the time he had finished his morning surgery until the evening. He had often no time for his meals, which, as a rule, were scratch meals. He admitted that the proposal would give greater confidence to the public, but it was impracticable; there were only a certain number of doctors in this country. If this extra duty were thrown on them they would undertake it, but it would be at the expense of their patients. It was a question of proportion. The only way to meet the case was that suggested in an amendment of which he had given notice. It suggested that, after consultation with the Government department, a special officer might be appointed for this particular purpose. His amendment proposed that the county boroughs might, where they wished, appoint such a special officer. He was very sorry that the society that entertained this fear of premature burial had not accepted the half-measure, but had gone out for the whole proposal in Mr. Peto's amendment. As so often happened, in aiming at the impracticable, the society had lost the half-loaf which he had offered. He opposed the amendment, as it was impracticable. He hoped it would be withdrawn, and that they would see what the Government suggested as an alternative.

Dr. Vernon Davies said that he had no hesitation in saying that so far as the towns were concerned and the districts near towns the proposal that the doctor should see the body after death was feasible. In twenty-three years' practice he had only failed once to see the patient after death. In country districts the matter was not so easy, as a doctor might have to travel twenty miles to see a body. If something could be done to meet the case of the country areas he would be prepared to support the proposal.

Sir Kingsley Wood (Parliamentary Secretary to the Ministry of Health) said that under the Act of 1874 a doctor in attendance on the deceased person in his last illness was required to give a certificate as to the cause of death to the best of his knowledge and belief. If there was no medical certificate the registrar at once referred the matter to the coroner, and if the death was due to an accident, an industrial disease, or other cause which was appropriate for consideration by the coroner, the registrar referred it to the coroner before registration. The certificate was thus, even in present circumstances, an important element in the evidence determining how the case was to be treated. A doctor it was not required to see the deceased person after death, nor was it essential for the purposes of a certificate that he should do so. In ordinary cases, where he had attended the deceased until shortly before death and was informed by a relative that death had taken place, that knowledge would enable him to certify the cause of death, provided this was consistent with the opinion he had formed of the disease. It would be a pity to imperil the useful provisions of this bill, which had been supported by all parties, because of a question of this kind. The steps that could be taken to meet the views of those who felt strongly on this matter had been considered. It was true that in about 40 per cent. of cases the doctor did not see the deceased after death; the difficulty of meeting the situation was very largely experienced in the rural areas. It

was difficult to impose not only on medical men but on the families of the deceased persons charges and expenses which in many cases they would resent. Therefore he suggested that the case might be met by the Registrar-General's office extending the system of the reference by registrars to coroners on the facts as disclosed by the medical certificate of the cause of death. If that policy was pursued as it was intended that it should be, the certificate would show whether the doctor had seen the deceased after death, and how long before death he last saw him alive; and it would thus be possible that any case not seen after death or a reasonably short period before death would come under review by the coroner before registration or burial. It was to be anticipated that this arrangement, in addition to bringing a large class of the more doubtful cases under special review, would greatly increase the proportion of cases seen by a doctor after death, and the improvement in that respect would be progressive to the extent of reaching by stages a standard which even Mr. Peto might regard as satisfactory. In order that the progress and success of this course of action might be properly watched the Registrar-General would obtain statistics showing the proportion of deaths certified by doctors who had seen the deceased after death, and these figures would be published in the Registrar-General's annual publication. The Minister of Health was also prepared to say that if the result of the action now proposed was ineffective he would be prepared to reconsider the whole question with a view to securing the object in view either by executive or legislative action.

Mr. Peto withdrew his amendment.

On the motion that the bill should be read a third time, Mr. Groves, in supporting the third reading, repeated his plea that the panel doctors should be required to view the body before certification.

Dr. Fremantle thanked the Ministry of Health and the House for supporting the bill. He said that the feature in which it would be found most useful would be the notification of stillbirths.

The bill was read a third time and passed; it will come into operation on July 1st, 1927.

#### Mental Deficiency Bill.

The Mental Deficiency Bill, which has passed the House of Lords, came on for second reading in the House of Commons on Monday night, November 29th. Mr. Chamberlain (Minister of Health), in moving the second reading, explained that the measure was very urgently required in the interests of mental defectives themselves. The real substance of the bill was to be found in the first clause, which extended the definition of defectives. Hitherto there had been difficulty in dealing with mental defectives who were not defective at birth or in early life. There had been some extremely painful and distressing cases of encephalitis lethargica where, as an after-effect, serious mental deterioration had taken place, but the boy or girl affected, not being of an early age, could not be dealt with under the existing law. The bill provided that cases of mental defectives, whether innate or induced after birth by disease, injury, or other causes, could be dealt with.

Calling attention to a number of amendments on minor matters to the existing law, designed to make it more complete, the Minister stated that Clause 6 dealt with local authorities. The present Act authorized combination of local authorities, but did not enable them to provide additional beds which could be lent to other authorities. Clause 6 of the bill permitted a local authority to build an institution of a size sufficient to deal with its own cases and to take in patients from other areas. The local mental deficiency authority and the local education authority could provide the institution jointly. It was hoped that mutual arrangements would be come to whereby the best use would be made of the provisions of the bill, which had the unqualified support of the Central Association for Mental Welfare. The bill did not in any way interfere with the safeguards provided in the Mental Deficiency Act of 1913. In addition to the general limitation in that Act, it was provided that there must be two medical certificates, one of which must be signed by a medical practitioner specially approved for the purpose. The case would then come before a judicial authority. That authority must be satisfied that the person was a defective and was a subject to be dealt with under the Act. At the end of a year, after the case had been dealt with in an institution, special medical and other reports had to be made and forwarded to the Board of Control. If the Board, after considering the reports and the means of care and supervision which would be available if the defectives were discharged, came to the conclusion that the continuance of the Order was required in the defective's interest, they could make an order continuing detention in the institution for another year. The same procedure was followed at the end of succeeding periods of five years each. In the case of a defective under 21 there was the further safeguard that visitors might, when the patient reached 21, discharge him if they thought his detention was no longer required in his own interest. In addition, all defectives detained under the Act were visited by members of the Board of Control from time to time. The bill did not diminish any of the existing safeguards.

Mr. Rhys Davies moved the rejection of the bill because it was not confined to children and because it would be wiser to wait until three committees now sitting had reported.

Mr. Morrison seconded the motion for rejection. After some discussion, Sir K. Wood (Parliamentary Secretary to the Ministry of Health), in reply, said that the bill would enable existing accommodation to be more usefully employed. He agreed that much care and attention should be given to the cases of mental defect after lethargic encephalitis. The bill provided that the treatment to be made available was, first, supervision; secondly, guardianship; and, thirdly, institutional care.

Dr. Vernon Davies expressed doubt whether the Minister of Health, in referring to encephalitis lethargica, had in mind elderly people. The bill referred to a condition of arrested or incomplete development of the mind. A man of 50, who got encephalitis lethargica and developed some of these awful symptoms afterwards, was not necessarily suffering from arrested development or incomplete development. It was a perverted development, and the great benefit of the bill was that it made it possible to take charge of these sad cases at whatever age. The bill ought to apply to people of any age.

Mr. Chamberlain replied that the question of people of later ages could be discussed in committee. His view was that clearly it was impossible at present to deal with all ages; it was only possible to deal with those mental defectives whose development had been arrested or rendered incomplete by one of the causes specified.

Dr. Fremantle said that he served on committees with the experts who drew up the distinction, or something like it, and submitted it to the Ministry of Health; they wished only to apply it to the adolescent, and did not intend to extend it to later ages when the number of cases was not sufficiently numerous.

Mr. Rhys Davies withdrew his motion for the rejection, and the bill was read a second time.

### Dogs for Research.

In reply to questions from Captain A. Evans and Captain P. MacDonald, concerning the conviction as a dog thief of a man who sold dogs to the University College School of Physiology, London, Sir William Johnson-Hicks said he had seen a press report of the case. He added that the college authorities had stated publicly that their procedure was to buy the animals when required from a general dealer in animals and animals' food, and to require from him a written guarantee that all the animals so purchased were legitimately obtained. The experiments carried on at the college were for the purpose of medical and scientific research, and were subject to the conditions and restrictions laid down by the Act 39 and 40 Vic., cap. 77. The laboratory was inspected at frequent intervals by the inspectors appointed under that Act.

Dr. Salter asked whether the Home Secretary would arrange for allocating to scientific purposes some of the 50,000 stray dogs taken charge of by the Metropolitan Police every year. The Home Secretary replied that he did not think it desirable at present that the police should enter into arrangements of this kind. The man in this case had been previously convicted, but he had no evidence that the college authorities knew that fact. Mr. Bromley asked whether the Government did not think it time to stop "this horrible practice, carried on under the cloak of science." The Speaker ruled out the question. Sir Robert Gower suggested an inquiry into the methods by which dogs and other animals were obtained for vivisection in physiological schools. The Home Secretary replied that he had received a communication from the responsible authorities of the school containing information as to the procedure adopted by them in the purchase of animals. This information, he understood, was not before the magistrate when he dealt with the case. Apart from this case, no complaints had reached him, and he saw no necessity for a general inquiry. The provisions of the ordinary law of larceny were sufficient to deal with thefts of animals. Sir R. Gower suggested that licences should be compulsory for persons dealing in dogs and cats. The Home Secretary said he could not answer without further consideration, for which at present he saw no need.

### Smoke Abatement Bill in Grand Committee.

Consideration of the Public Health (Smoke Abatement) Bill was resumed in Grand Committee on November 23rd. On a clause which provided that, to ensure the reduction of smoke, urban authorities might make by-laws regulating the heating arrangements in new buildings other than private dwelling-houses, Captain Waterhouse moved to extend this power to new private dwelling-houses. Dr. Fremantle said advocates of smoke abatement admitted that it was impossible to deal at present with the nuisance in existing houses. They thought they should try to regulate the fireplaces of houses to be built under the Government schemes, but in the name of public health he protested against the idea that the local authorities might construct houses without open fireplaces. The authorities might thereby promote the interests of their electrical or gas undertakings, but Professor Leonard Hill, the greatest authority in the country on the subject, had declared for the open fireplace against systems which heated by convection or radiation, but did not ventilate. Dr. Fremantle asked what the Ministry of Health was doing at its building laboratory to investigate the proper placing and construction of fireplaces. Mr. Greenwood said some local authorities had constructed houses so as to prevent a new smoke nuisance. Mr. Lunn said he had never had a headache till he came to London and sat by a gas fire. Commander Asbury said they all knew that gas fires were unhealthy. Mr. Chamberlain agreed that domestic smoke produced more nuisance than industrial smoke. They now had 8,000,000 houses in this country, none of which would be affected by the bill. New houses were being built at the rate of 200,000 a year, mostly by authorities who did not need to enact by-laws against themselves. Local authorities were fitting 75 per cent. of their new houses with arrangements for cooking or heating by gas or electricity. Mr. Dalton asked if the Ministry was experimenting with smoke-consuming grates. The Minister said

that it was. The amendment to include dwelling-houses was defeated, but on the motion of Sir Arthur Holbrook local authorities were empowered to make smoke abatement by-laws regulating cooking apparatus in buildings other than private dwelling-houses.

On the clause authorizing local authorities to make by-laws against noxious smoke, Mr. Chamberlain said the Ministry could not lay down legal definitions of smoke, but scientific standards might later be established. Mr. Womersley asked whether noxious vapours from fish-meal works and fertilizer works would come under the bill. Mr. Chamberlain pointed out that the bill provided that the Minister of Health could schedule the emission of noxious gases of any kind and could send his inspectors to examine the works. The clause authorizing this was carried after Dr. V. Davies had said that bad smells were not necessarily noxious; some did people good. On the other hand, an invisible scentless emission might damage health and vegetation.

The Committee stage was completed on November 24th. A clause excluding ships from the operation of the bill was amended to make the bill apply to ships other than those habitually used as ocean-going vessels. A subsequent clause proposed that any local authority observing a smoke nuisance on premises occupied for the public service of the Crown should report it to the appropriate Government department, which should cause steps to be taken for its abatement. Mr. Lunn moved to add that if the nuisance was not abated or recurred it should also be reported to the Ministry of Health. Sir Kingsley Wood opposed the amendment; it did not, he said, arm the Minister of Health with power to deal with other Government departments. Dr. Fremantle said the amendment reminded the Committee that the Ministry of Health was established to supervise the health of the country generally, but had no power to look into any question affecting the health of persons in any other Government department. Some machinery should be provided to enable the Minister to supervise the Acts for which he was mainly responsible as a whole, and not only those parts which he had to administer. In the army what corresponded to the Ministry of Health had power to look into every department and to make representations; the separate departments remained responsible for carrying them out. There ought to be some such system in civil life. Sir Kingsley Wood said it never had been intended that if small-pox or scarlet fever broke out among the clerks of, for instance, the War Office, medical officers of the Ministry of Health should attend to it. The amendment was withdrawn. A new clause was added giving power to local authorities, singly or in combination, to make researches into atmospheric pollution and the abatement of smoke nuisances, and to contribute towards the cost of researches by other bodies or persons.

**Infantile Paralysis.**—In reply to a question asking the Minister of Health whether it was desirable, when an epidemic occurred in a school, that it should be closed, Mr. Chamberlain said that was a request for an expression of personal opinion. He had no powers to deal with the closing of schools. In answer to another question, he said that no other public school than Uppingham had been attacked by infantile paralysis.

**Foot-and-Mouth Disease.**—The Netherlands Government has furnished the British Ministry of Agriculture with details of experiments in Holland which are claimed to show that the virus of foot-and-mouth disease, existing in the flesh of animals infected by that disease, is destroyed by the lactic acid which in a short time develops in the dead tissues. The Dutch experiments dealt with flesh only, but the British Ministry is conducting experiments on the duration of the virus in all parts of the animal, and results have already been obtained indicating that certain parts of the carcass remain infective. In these circumstances the Ministry was not prepared to remove the prohibition of the import of fresh carcasses from countries infected with foot-and-mouth disease.

**Ventilation of Underground Shelters.**—Sir L. Worthington-Evans, on November 30th, replying to Mr. Thurtle, who asked what was the object of the recent action of his department in sending a company of soldiers into the London postal tube and keeping them there for a number of hours, said that the experiment was designed to furnish data regarding the ventilation required under certain conditions in underground shelters, such as dug-outs.

### Notes in Brief.

The Home Secretary is not satisfied with the present strength of the factory inspectorate, and as soon as the factories bill has made substantial progress proposes to set up a committee to make a comprehensive survey of the position.

Milk brought from Ireland, the Channel Islands, and the Isle of Man will not come under either the Public Health (Imported Milk) Regulations or the Milk and Dairies Order.

Up to and including September 30th, 1926, 209,685 widows' pensions had been applied for. Of these, 161,309 were awarded and 44,930 rejected. For the same period, 15,375 orphans' pensions were asked for; 11,123 being granted and 3,433 rejected.

Mr. Amery (Secretary for the Colonies) states that the progressive establishment of a chain of tropical research stations has been recommended by the Imperial Conference to the consideration of the Governments concerned.

The Home Secretary has under consideration the extension of the police returns for 1927 to include further particulars of the persons killed by vehicles on the road or as passengers in such vehicles.

On November 30th the Lords' Amendment to the Lead Paint (Protection against Poisoning) Bill was agreed to by the House of Commons.

## Universities and Colleges.

## UNIVERSITY OF OXFORD.

## Radcliffe Travelling Fellowship.

AN examination for a Radcliffe Travelling Fellowship of the annual value of £300, and tenable for two years, will be held during Hilary term, 1927, at the University Museum, commencing on February 15th. Candidates must have passed all the examinations required by the University for the B.A. and B.M. degrees. They must not have exceeded four years from the time of passing the last examination required for the degree of B.M. The successful candidate must before election declare that he intends to devote himself during the period of his tenure of the fellowship to the study of medical science and to travel abroad with a view to that study. The fellowship will be vacated *ipso facto* by a Fellow who spends more than nine months in the whole within the United Kingdom. The Regius Professor of Medicine and the examiners present a yearly report on the work done by each Fellow to the electors, who may, if they think the report unsatisfactory, declare the fellowship forfeited. The fellowship is open to women.

The examination will occupy four days. Papers will be set in physiology, pathology, and preventive medicine, and a subject will be proposed for an essay. There will also be a practical examination in pathology. A candidate desiring to offer in addition a special branch of either medicine or surgery must send notice of this to the Regius Professor by February 2nd. Intending candidates should send their names, addresses, qualifications, etc., to the Regius Professor of Medicine, University Museum, by February 2nd.

At a congregation held on November 27th the following medical degrees were conferred:

D.M.—E. G. T. Liddell.  
B.M.—J. de la M. Savage.

## UNIVERSITY OF BIRMINGHAM.

Dr. F. A. PICKWORTH has been appointed director to the Joint Board of Research for Mental Diseases in the City and University of Birmingham, in place of the late Sir P. W. Mott. Dr. Pickworth received his medical education at Charing Cross Hospital, obtained the diplomas M.R.C.S., L.R.C.P. in 1921, and graduated M.B., B.S. in 1922. His previous appointments included those of house-physician to Charing Cross Hospital and research officer and pathologist to the Birmingham Joint Board of Research.

## UNIVERSITY OF LEEDS.

MR. J. S. YOUNG, M.A., B.Sc., M.B., Ch.B. Glasg., has been appointed lecturer in experimental pathology and assistant director of cancer research, and Mr. H. J. Channon, B.A., M.Sc. Lond., biochemist in the Department of Experimental Pathology.

Cancer Research Fellowships have been awarded to Miss Georgiana M. Duthie, M.D. Manch., who has been a demonstrator in the pathology department of the University since January, 1925, and to Mr. G. A. Collinson, M.Sc. Leeds, who during the same period has acted as research assistant to Sir Berkeley Moynihan.

They were made as follows:  
M. Duthie, demonstrator in biochemistry;  
M. Collinson, assistant in physiology;  
and Mr. F. C. Happold, M.Sc. Manch., demonstrator in pathology and bacteriology.

## VICTORIA UNIVERSITY OF MANCHESTER.

THE following have been appointed members of the Board of the Faculty of Medicine: Dr. William Dyson, O.B.E., Dr. D. S. Sutherland, and Mr. S. R. Wilson, M.B., B.S., F.R.C.S.

## UNIVERSITY OF GLASGOW.

At the graduation ceremony on November 20th the degree of M.D. was conferred on Evelyn M'Pherson.

## The Services.

## COMMISSIONS IN THE R.A.M.C.

COMMISSIONS in the Royal Army Medical Corps, not exceeding twenty-five in number, will be offered by nominations allotted to the medical schools in January, 1927. A certain number of nominations will in addition remain at the disposal of the War Office. Candidates must be under 28 years of age on January 31st, 1927. The names of those nominated, and applications for consideration, must reach the War Office not later than January 10th. The list of medical schools to which nominations have been allotted and further information will be found in our advertisement pages.

## EXAMINATION FOR DENTAL OFFICERS R.N.

AN examination for dental surgeons for entry into the Royal Navy will take place at Guy's Hospital Dental School, London Bridge, S.E.1, on January 4th, 1927, and the following days. Nine appointments are offered for competition. Further particulars will be found in our advertisement columns.

## Medical News.

DR. GUSTAV MONOD, physician to the Thermal Hospital at Vichy, has been appointed Chevalier of the Legion of Honour. Dr. Monod, who is M.R.C.P. Lond. as well as M.D. Paris, is delegate for Great Britain of the Association for the Development of the Medical Relations of the Faculty of Medicine of Paris; he is also, as our readers know, our French Correspondent.

A SERIES of lectures and practical courses of instruction for the diploma of psychological medicine will commence at the Maudsley Hospital, Denmark Hill, S.E.5, on Tuesday, January 4th, 1927. Part I of the series, in addition to practical instruction and demonstrations, will comprise twelve lectures on the physiology and anatomy of the nervous system by Dr. F. Golla, pathologist to the London County Council and Director of the Central Pathological Laboratory, Maudsley Hospital, beginning January 7th; four lectures on the histology of the nervous system and the endocrine glands by Dr. C. Da Fano, reader in histology in the University of London, commencing on January 4th, and eight lectures on psychology by Dr. Henry Devine, medical superintendent of the Holloway Sanatorium for the Insane, beginning January 6th. Part II will follow in March, and will consist of a further series of lectures and demonstrations. The fee for the whole course of Parts I and II is 15 guineas, for Parts I and II separately 10 guineas, for one single lecture in Part I or Part II 4 and 2 guineas respectively. Inquiries should be addressed to the Director of the Central Laboratory, Maudsley Hospital, Denmark Hill, S.E.5.

A THREE months' course of lectures and demonstrations on clinical practice and in hospital administration will be given at the North-Eastern Hospital of the Metropolitan Asylums Board, Tottenham, by Dr. F. H. Thomson, medical superintendent, beginning January 3rd, 1927. Particulars can be obtained from the Clerk to the Board, Victoria Embankment, E.C.4.

AT the meeting of the Post-Graduate Hostel to be held at the Imperial Hotel, Russell Square, on December 7th at 9 p.m., Mr. Clifford Morson will discuss peccant prostate; on Thursday, December 9th, at the same hour, a discussion on carcinoma of the oesophagus will be opened by Sir Charters Symonds. Dr. Arnold Chaplin will read a paper on the medical service at sea in the mercantile marine, on Friday, December 10th, at 9 p.m. Dinner (price 5s.) will be served at 8 p.m. All medical practitioners are welcome.

THE Fellowship of Medicine announces that on December 4th, at 5 p.m., Mr. L. Bathe Rawling will deliver a lecture at the Medical Society, 11, Chandos Street, W.1, on injuries to the head; open to all members of the medical profession without fee. On December 6th the Infants Hospital will begin a fortnight's afternoon course. Practical courses in obstetrics can be arranged at Queen Charlotte's Hospital to occupy a fortnight or a month; every week the City of London Maternity Hospital holds a course in obstetrics and child welfare; personal application must be made to the Fellowship offices; the Fellowship can also arrange clinical assistantships at the Samari Hospital. The following courses will be held next month: a fortnight's intensive course in medicine, surgery, and the specialties at the Prince of Wales's General Hospital, from January 10th to 22nd; a fortnight's all-day course in cardiology at the National Hospital for Diseases of the Heart, from January 17th to 29th (entries limited to twenty); a fortnight's course in diseases of children at the Royal Free Hospital and the Children's Clinic, from January 10th to 22nd; and a month's course (Tuesday and Saturday mornings at 11) in psychological medicine at the Bethlehem Royal Hospital from January 11th to February 5th. A further series of lectures on medical and surgical emergencies will be held under the auspices of the Fellowship of Medicine, and there will also be a series of clinical demonstrations in ophthalmology at the Royal Eye Hospital; particulars to be announced later. Copies of all syllabuses of the special courses, a programme of the general course of work, and the *Post-Graduate Medical Journal* can be obtained from the Secretary of the Fellowship, 1, Wilton Street, W.1.

THE autumn dinner of the Irish Medical Schools' Graduates' Association was held at the Savoy Hotel on November 23rd. Sir W. I. de C. Wheeler, the president, was in the chair, and the guest of honour was the Right Hon. Thomas Molony, the late Lord Chief Justice of Ireland. The toast of "The Guests" was proposed by Sir John William Moore and responded to by Sir Thomas Molony and Lord Shaw of Dunfermline. The toast of "The President Association" was proposed by Dr. R. Travers Smith. Sir William Wheeler responded. The success of the dinner was enhanced by a delightful musical programme.

DEC. 4, 1926]

# LETTERS, NOTES, AND ANSWERS.

## Letters, Notes, and Answers.

THE annual dinner of the Yorkshire Association of Glasgow Graduates will be held in the Great Northern Hotel, Leeds, at 6.45 p.m. on Friday, December 17th. The guest of the evening will be Mr. Farquhar Macrae of Glasgow. All old Glasgow graduates resident in Yorkshire are invited to the dinner, particulars regarding which may be had on application to the honorary secretary, Dr. W. MacAdam, 40, Park Square, Leeds.

THE Tropical Disease Prevention Association is issuing an appeal for subscriptions to enable it to depute Dr. Louis Sambon and his fellow workers to investigate further the subject of cancer houses. Dr. Sambon, working under the auspices of the association named, carried out investigations in northern Italy, which he reported in the *Journal of Tropical Medicine and Hygiene* last August. The observations he made are held to justify the use not only of the term "cancer houses," but even of such phrases as "cancer streets" and "cancer villages." The facts are thought to support the suggestion that there is an unequal distribution of some element in the environment (whether it be a parasitic organism or other) which may be a predisposing or even a causative agent. The appeal is signed by Lord Aberconway and a number of well known men of medicine and science. Subscriptions may be sent to Mr. J. E. Russell, treasurer, at the National Bank, 101, Baker Street, London, W.1.

AT the meeting of the Hunterian Society of London on Monday next, December 6th, at Simpson's Restaurant, Cheapside, a discussion on the nervous child will be opened by Dr. H. C. Cameron and Dr. Bernard Myers at 8.30 o'clock.

AT the meeting of the Harveian Society of London at Paddington Town Hall on Thursday, December 9th, at 8.30 p.m., a discussion on the etiology of high blood pressure and the respiratory phenomena associated with high blood pressure and chronic nephritis will be opened by Sir John Poynton, Dr. Parkinson, and Dr. de Wesselow.

THE Medical Society of the Mediterranean Coast has arranged a tour from December 6th to 24th, visiting Hyères, St. Raphael, Cannes, Grasse, Nice, Mentone, Monte Carlo, Monaco, and Beaulieu, open to all medical practitioners, their families, and students in so far as accommodation allows. The cost, including hotels and motor-car excursions, is 1,050 francs, apart from the cost of the railway journey outwards to Toulon and homewards from Nice. Further information may be obtained from the Office Français du Tourisme, 55, Haymarket, S.W.1.

THE buildings, in Endsleigh Gardens, W.C.1, of the Wellcome Bureau of Scientific Research and the Museum of Medical Science have been reconstructed and will be reopened on Wednesday next, December 8th, at 3 p.m., by Mr. Neville Chamberlain, Minister of Health. Afterwards Sir Walter Fletcher, M.D., F.R.S., Secretary to the Medical Research Council, will give an address on research and citizenship.

MESSRS. WILLIAM HEINEMANN (Medical Books) announce for immediate publication the fourth edition, in two volumes enlarged and revised, of Jacobi's *Atlas of Dermochromes*, with a new and original text by Henry MacCormac, C.B.E., M.D., F.R.C.P.

IN view of the heavy demand for facilities for undergraduate instruction which has been experienced at the National Hospital for Diseases of the Heart, Westminster, W.1, arrangements have now been made for the practice of the hospital to be open to medical students as from January 1st, 1927, at half the fees charged to graduates.

ON his retirement from the medical officership to the Post Office staff at Carnforth, after more than forty years' service, Dr. E. S. Jackson was presented by past and present employees and friends with a microscope.

DR. GEORGE WYNDRHAM CROWE has been presented by the past and present members of the Worcester police force with a handsome silver salver upon his retirement from the post of police surgeon after forty-eight years' service. Dr. Crowe, who lives in the house occupied by the founder of the British Medical Association, Sir Charles Hastings, was local secretary of the Jubilee Meeting of the Association held at Worcester in 1882.

A TURKISH pharmacopoeia has been introduced by the Turkish Government at Angora in place of the French codex hitherto in use.

A MONUMENT to Professor Chauveau was unveiled at the National Veterinary School at Lyons on November 7th.

A CHAIR which had belonged to the late Lord Lister was stolen, on November 16th, while in transit from the Shetland Islands to the Wellcome Historical Medical Museum. It had been made from the operating table of the old Edinburgh Infirmary, and was the property of Sir Watson Cheyne. It has now been recovered.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.** ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication. Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager. The **TELEPHONE NUMBERS** of the *British Medical Association* and *British Medical Journal* are **MUSEUM 9361, 9362, 9363, and 9364** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:  
The *British Medical Journal*, Aitiology Westcent,  
London.  
EDITOR of the *British Medical Journal*, Aitiology Westcent,  
London.  
FINANCIAL SECRETARY AND BUSINESS MANAGER  
(Advertisements, etc.), Articulate Westcent, London.  
MEDICAL SECRETARY, Medisera Westcent, London.  
The address of the Irish Office of the *British Medical Association* is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

## QUERIES AND ANSWERS.

**LICE ON DOGS.**  
A. J. C. T.—Many different drugs are recommended for the treatment of lice on dogs; a solution of potassa sulphurata in warm water is excellent if the dog can be washed out of doors, but owing to its objectionable odour it is not suitable if the dog has to be washed indoors. Fresh pyrethrum powder dusted into the dog's coat and brushed out after a few minutes is generally sufficient to remove the lice, but as it only stupefies the insects, the brushings must be immediately repeated. "Laval," a proprietary preparation manufactured by Cooper's Dip, is one of the best washes for general ecto-parasites in dogs and is non-toxic. None of the drugs in present use are capable of destroying the "nits," and the treatment must be repeated in about a week. Bedding should also receive attention, as the eggs are often deposited on the bedding material and the larvae reach the dog in this way. In addition to the above measures, any of the usual disinfectants in common use—except the carbolic series of disinfectants, which are very toxic to dogs—may be used in dilute solution.

**CHILBLAINS.**  
DR. A. MACBETH ELLIOT (London, W.) sends a note on the treatment of chilblains (erythema pernio) by ultra-violet light. He says: "Until recently I have had the same unsatisfactory results with whatever line of treatment I adopted in cases of chilblains. Early in October I had my first case this winter—a married woman who had been a martyr to chilblains all her life; both hands and feet were affected, and she was hardly free through the winter. Ultra-violet radiation with quartz mercury vapour lamp to the fingers and toes and to the legs and arms with the tungsten lamp gave immediate relief. After four radiations the condition had cleared up, and so far there has been no return. In another case in a woman giving the same history as above, but the feet being the more painful, all local signs had disappeared at the end of ten days. No other treatment was administered during the radiation; high frequency ionization, diathermy could be employed to supplement it if necessary, and in the past I have had temporary relief with these, but never anything like the results with ultra-violet radiation. Needless to say, each case must be treated on its merits; ultra-violet radiation requires very careful supervision."

DR. F. A. E. SILCOCK (Leicester) recommends the use of luminous heat-ray treatment in combination with the ultra-violet light. "I have," he says, "treated many cases with very satisfactory results by using a Bach mercury vapour ultra-violet and a Bollux luminous heat-ray lamp, concurrently focused on the affected parts. By this method the relief of the pain appears to be quicker and natural sunlight is much more closely imitated."

DR. SIDNEY MATTHEWS (Crawley) is induced by the mention of ultra-violet treatment of chilblains to say that he has found advantage from ultra-violet treatment in Raynaud's disease. He has a case of the second degree under treatment.

DR. A. H. MACDONALD (London), who is inclined to think that chilblains come under the heading of a deficiency disease, recommends the following general line of treatment for the child who has to walk half a mile or so to school. Those who only go a short distance and then sit down to lessons suffer more frequently. It will be found advisable on arrival at school that a quarter of an hour should be spent in tramping round, so as to set the circulation going. (2) Cod-liver oil should be given to

those who are known to suffer in this way in the winter. (3) Milk at 11 a.m.—a quarter to half a pint. (4) Some fresh fruit every day. These measures will prevent chilblains in most cases. To heal them ultra-violet rays are a great aid, and it is fortunate that we have this extra means now at our disposal to cure this complaint. The giving of calcium salts I have found to be disappointing, but the help given by (2), (3), and (4) goes a long way towards preventing this trouble.

#### INCOME TAX.

##### Assessment of Practice.

"C. W. S." is part proprietor of a practice which has been assessed on the cash basis for thirty-five years. The authorities now desire to change to the basis of "fees earned"—less, presumably, an allowance for probable bad debts—and further to revise the assessments already made from 1920-21 onwards.

\*. As we have always admitted, the cash basis is not technically correct in strict law, and its acceptance is based on mutual convenience and on the assumption that in the long run the results derived from the two methods are substantially the same. "C. W. S." is willing to agree to an alteration for the current year, but we think he is acting only reasonably in objecting to the reopening of the liability for previous years. Assuming that there have been no special circumstances which have rendered the cash basis unfair to the revenue, and bearing in mind that inspectors of taxes have accepted that basis in the past and that in doing so they have followed a common practice within the cognizance of the authorities, we suggest that, if the local inspector continues to press for a revision of past assessments, "C. W. S." should place all the facts before the Secretary, Board of Inland Revenue, Somerset House, W.C.2, and ask that the local official should be authorized not to insist on the application of the "fees earned" basis to years prior to 1926-27.

##### Depreciation of Motor Cycle.

"F. M. W." has been informed by the inspector of taxes that "depreciation in respect of the motor cycle is not allowable as an expense if repairs, etc., are allowed."

\*. The statement seems to be based on a misunderstanding. The depreciation allowance excludes a claim to deduct the cost of replacing the vehicle used, but not running costs. It must surely be obvious that such expenses as petrol, oil, licence, and replacement or repair of parts are allowable, however the gradual exhaustion of the vehicle by wear and tear may be dealt with in the returns.

#### LETTERS, NOTES, ETC.

##### AN APPEAL.

DR. HILDRED CARLILL (Physician to Westminster Hospital) writes from 146, Harley Street, W.: "A medical man, aged 70, who has no knowledge of this appeal, is sorely pressed. Twenty years ago he was advised on medical practice. He has been able to act, but is in indistinct health. Of four sons who would now all be helping, three died at the age of 21 (one, my friend in another ship, in the *Queen Mary* at Jutland, and one of cerebro-spinal meningitis at St. Omer). The remaining boy is in the air branch of the navy, and he sends home the little he can afford. Recently a prolonged illness, lasting over four months and necessitating several operations, has prevented the doctor from earning a penny, and his financial state is critical. A friend has opened a subscription list with £50, and I, who know the facts, shall be very glad to receive, acknowledge, and forward subscriptions from sympathetic professional colleagues. Perhaps someone may know of an opening for the doctor on the clerical side of a hospital or its appeal department, or of a medical or other society. He aspires only to a small living wage, and for this he would do first-rate work."

##### THE CANCER PROBLEM.

DR. A. T. BRAND (Driffeld), in the course of a letter on this subject, writes: Dr. Gye, in his interesting lecture published in the *JOURNAL* of November 13th, states that he has succeeded in isolating a "living filterable microbe" which he believes to be the cause of new growths; but he insists that the microbe can only act in conjunction with an accessory chemical substance, which determines the special characters of the resulting cancers. I maintain that, since cancer does not arise in the perfectly healthy subject, there must be a predisposing condition precedent in every case before the causal microbe can attack successfully. One of the chief predisposing agents is prolonged irritation, which prepares the soil for the reception of the micro-organism. The special characters of the resulting cancers depend on the variety of tissue involved. Nor is the filterable virus described by Dr. Gye the only form of the microbe responsible for cancer. Several years ago both Dr. T. J. Glover of Toronto and Dr. J. Young of Edinburgh isolated and cultured, from every variety of malignant disease, the same micro-organism, which they found to be pleomorphic, its life cycle consisting of bacillus, coccus, spore sac, all easily visible under

the microscope, and a filter-passing phase, which is ultra-microscopical under ordinary circumstances, but evidently the same as the filterable virus of Dr. Gye, rendered visible by the special method of Mr. Barnard. Dr. Glover scrupulously refrained from making his researches known until he had completed them to his satisfaction, but now he has made a full communication, which has been published in the November issue of the *Canada Lancet and Practitioner* of Toronto. In this communication Dr. Glover describes his discovery, the isolation and culture of the micro-organism, the successful propagation of the disease from culture among the lower animals of all kinds, the injection of the toxin of the organism into the horse, resulting in the production of an antitoxin which he has used for diagnosis, prophylaxis, and treatment, concluding with a detailed account of fifty cases of successful treatment of advanced disease.

##### A LONDON CLINIC FOR PHYSIOTHERAPY.

THERE will shortly be opened in London, near Victoria Station, an out-patient clinic (to be called "The London Clinic") for the study and practice of "physical" treatment. The medical staff will be entirely honorary, and the treatment, we are informed, will be available for those who cannot afford to pay for its private administration. Courses of lectures and practical instruction will be held for doctors and medical students. There will also be courses for hospital nurses, and for masseuses. Each department will be supervised by one or more medical men who have specialized in the particular branch, and an honorary medical director will co-ordinate the work of all. There will be two large artificial light departments, one for women and children, the other for men, each equipped on a scale that will enable them to treat 1,000 patients in a day, and the clinic will gladly extend to insurance practitioners and school doctors facilities for the attendance of debilitated school children. The light treatment will be administered solely by generally trained hospital nurses, and the treatment in the electricity department, also under medical control, will be given by masseuses holding the medical electricity certificate of the Chartered Society of Massage and Medical Gymnastics, and those who hold this certificate will be eligible for a special course and examination in "orthopaedic electricity." This course is designed to turn out a masseuse competent to treat orthopaedic disabilities, including the effective stimulation of muscles or groups of muscles. The work of this department will thus consist of the ordinary "medical" electricity and "orthopaedic" electricity. There will be a special department for diathermy applied to certain conditions in women, such as dysmenorrhoea and infective cervicitis; this treatment will be administered by the medical officer himself. Massage will be co-ordinated with the electricity department, and remedial exercises will have an important place. A covered exercise ground is being constructed, and the Margaret Morris system of exercises has been selected as specially suitable for classes of children, supervised by Miss Morris. The clinic has been made possible by the generous support of the Medical Research Council, which has guaranteed the maintenance of the clinic. The medical staff will be advertised in due course in the medical journals. The present nucleus staff consists of Dr. G. Murray-Levick (medical director), Mr. J. F. Carter Braine, F.R.C.S., Dr. L. D. Bailey, M.C., Dr. E. F. Cumberbatch, and Dr. C. A. Robinson.

##### PUBLIC HEALTH IN GERMANY.

DR. BINNIE DUNLOP (London, S.W.7) writes: Professor Abel is reported (November 6th, p. 846) as having said that "in Germany the last figures showed that the population had diminished in a year by half a million." According to my notes he said that Germany's population was still increasing. In any case, one of his charts showed that the birth rate and death rate per thousand of the population had been approximately 36 and 21 in 1900, 28 and 16 in 1913, 22 and 12 in 1925—representing in 1925 an addition of about 670,000 inhabitants. Why, it might be asked, did the death rate fall thus? Surely it was mainly because the declining birth rate continually reduced the proportion of badly nourished persons; and this contention is supported by the dramatic rise of the tuberculosis mortality in Germany during the war which Professor Abel demonstrated.

\*. "Diminished" was a slip of the pen. The increased tuberculosis mortality experienced not only in Germany but in other European countries, including England and Wales, is commonly attributed to the diminished food supply. The Malthusians would probably attribute the fall in the death rate of Germany to a reduction in the proportion of badly nourished persons, but a more widely accepted view is that the improvement of sanitation and of the well-being of the population generally, including better nutrition, is responsible.

##### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 66, 67, 68, 69, 72, and 73 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 70 and 71.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 239.

DEC. 11, 1926]

## SECTION OF SURGERY.

British Medical Association.  
PROCEEDINGS OF SECTIONS AT THE ANNUAL  
MEETING, NOTTINGHAM, 1926.

## SECTION OF SURGERY.

Sir D'ARCY POWER, K.B.E., M.B., F.R.C.S., President.

## DISCUSSION ON CARCINOMA OF THE TONGUE.

## OPENING PAPERS.

I.—DUNCAN C. L. FITZWILLIAMS, C.M.G.,  
M.D., Ch.M. Edin., F.R.C.S.,

Surgeon to and Lecturer on Surgery, St. Mary's Hospital, London.

## THE SURGICAL ASPECT.

## Preliminaries.

THERE is hardly any situation in the body in which the success of the operation and the comfort of the patient depend more upon the preliminary attention and training of the patient than in cancer of the tongue.

The buccal cavity is a septic cavity; it is more septic where ulceration is taking place or where carious teeth, pyorrhoæa, and other obvious foci of sepsis are present. The effect of sepsis, as in the case of other poisonous drugs, is a matter of dose and concentration. A small dose of morphine may be beneficial; a larger one produces deep sleep; and a still larger one kills the patient. A small dose of sepsis produces a slight elevation of temperature, and is often seen after so-called aseptic operations; a larger one produces rigors, breaking down and suppuration of wounds, according to its intensity; a still larger one causes pyæmia and the death of the patient. As, therefore, we cannot altogether eliminate sepsis from our procedure in the mouth, we must diminish the dose as much as possible.

All carious teeth or teeth around which there is suppuration in the gums should be removed, also septic tonsils. A strong antiseptic mouth-wash of carbolic should be used constantly for some days by the patient. A very good and pleasant mouth-wash is the following: Phenol pur. 1 oz., tinct. lavender 2 oz., water to 6 oz.; 1 oz. to a tumbler of warm water. This mouth-wash should be held in the mouth for some time, the patient breathing through the ulcerated tongue on the tongue can be dried and the ulcerated surface touched with a pledget of cotton-wool or a brush dipped in pure carbolic acid or 20 per cent. chromic acid twice a day, taking care that none of the acid spreads beyond the ulcer. In this way we can ensure that the buccal cavity contains as few septic organisms as possible.

The operation will upset the important function of swallowing, and to a less extent breathing and coughing. We little realize how much we are dependent on the action of swallowing for our comfort. Not only do we swallow food, but we are constantly swallowing saliva. The flow of saliva we can diminish by rinsing the mouth out with an astringent, such as an infusion of orange peel.

After the operation for removal of the tongue swallowing is completely upset: the liquids taken through the mouth must be poured down by means of a feeding cup and long rubber tube which extends to the back of the throat. There is always some difficulty in tolerating things at the back of the throat and guiding fluids past the opening of the glottis. This should be acquired by practice some days before the operation. The patient takes the feeding cup in one hand and passes the tube into the pharynx; the tube is pinched by the other hand and the cup tilted; by relaxing the tube fluid is allowed to flow into the throat and is swallowed. Some practice is needed. For these reasons it is better that the patient should go into a nursing home for a few days before the operation. In many advanced cases the man is enfeebled by pain, inability to swallow, sleeplessness, and the continual absorption of sepsis. These should be obviated as far as possible. His health should be sustained and improved by good food, enemata being given if thought necessary; sleep should be procured by sedatives, and the measures just detailed followed to finish the oral sepsis. A rest in bed for part of the day will do him good.

There is always some difficulty in getting a patient to submit to these measures, as, having made up his mind to undergo an operation, he wants it performed at once. An operation is not a pleasant thing to look forward to; he knows it must bring him considerable discomfort; it is not without risk, but having once screwed himself up to the point he wishes to diminish the period of anxiety. He does not appreciate or pay any attention to the preliminaries which are so necessary for success. This is natural in an elderly individual whose peculiarities, crotchets, and eccentricities have all been exaggerated by a painful illness. A patient who can take a placid and common-sense view of the proceeding and who will help the surgeon is a great asset; this attitude goes a long way towards recovery.

## Choice of Operation.

The first thing to be decided upon is whether the operation can be an intrabuccal operation, such as that which we associate with the name of Whitehead, or whether it has to be one which demands division of the jaw, to which the name of Syme is attached.

This may be left to the individual view of the surgeon, but we are all guided by the fact that an intrabuccal operation is suitable for every case in which there is no extension to the floor of the mouth, no implication of the lower jaw, and no involvement of the anterior pillar of the fauces, tonsil, or palate; and perhaps we might add where the growth is not situated too far back upon the tongue. In cases where the growth has extended to these situations there is no doubt that division of the jaw may give better access. Over a large number of cases of operation collected from different sources the difference in operative mortality between the two operations is very marked, that of the intrabuccal operation being exactly one-quarter that of the operation requiring division of the jaw.

## Methods of Approaching the Operation.

These are perhaps the most important points in what I am going to say. I am going to ask you to throw upon the scrap-heap almost the whole of the ordinary procedure of the usual operation.

I think I may say that the usual procedure for an intrabuccal operation is the following: An incision is made in the neck, the lingual artery is tied, the submaxillary gland removed and any carotid glands which may be seen; the tongue is then removed. The wound in the neck, so that it as a rule, communicates with that in the neck, so that it is advisable to have the neck dissection as small as possible. If the whole tongue has to be removed the same procedure may take place upon both sides of the neck—a long and trying operation for an old man. The operation is not difficult, and almost any careful surgeon can carry it out with a very small operative mortality. The after-history, however, is melancholy in the extreme. It is not too much to say that the after-results are as bad as any we have in surgery. This, in my opinion, is due solely to the procedure adopted, and I do not think any modern surgeon would approach the problem in this way if he was not guided and bound by tradition and want.

The operation consists in removing the growth and the lymphatic field. This cannot be done adequately at one operation, as the mouth and the neck will communicate, and there will be a huge septic wound. It must, therefore, be done in two stages; it is obvious that the neck dissection, which is almost more important as regards prognosis than the mouth operation, must be as thorough as possible, and accordingly should not be handicapped by the scar tissue of a previous operation. This at once brings us to the question of the ligation of the lingual artery, and here I may say that I believe the ligature of the lingual artery will soon become a discarded procedure: it has had its day, and is no longer necessary. At a time we can all remember, when the surgeon, the assistant, and the anaesthetist fought for the temporary possession of the patient's mouth, there was a constant risk of blood being sucked into the larynx, and the control of hæmorrhage was of vital importance; now, however, with the laryngotomy tube and the pharynx plugged, it is of no consequence. Having, therefore, done away with the ligature of the lingual artery, would any surgeon proceed

to perform a preliminary dissection of the glands in the neck in an adequate manner with the knowledge that the fascial planes were liable to be infected from the mouth? If he were tempted to do it on one side, would he do it on both? The answer is, Never.

A dissection of the neck is an operation which should be complete, and not a mere adjunct to the ligation of the lingual artery, as it now is in many cases. It is an operation which ought to be thoroughly carried out, and the whole gland-bearing fascia of the neck should be cleared from the great vessels. This is the one chance we have of dissecting in the undisturbed fascial planes, and no subsequent operation can be anything like as easy and as thorough. It is a long operation, and doubly so if both sides of the neck are to be dealt with. Moreover, considering the stage of the disease in which we see most of our cases, the safety of the patient lies entirely in the thoroughness with which this part of the operation is performed.

I believe that the proper method of dealing with the situation is to remove the tongue locally, first, as widely as is thought necessary, and then let the mouth wound heal, and a fortnight later deal with the neck. The flow of lymph during that fortnight must be very slight, as the site from which it flows is removed. Spread of the disease during that time is not to be feared, as the cancer is no longer present. This is far better than doing the neck first, and at the same time taking the opportunity of ligating the vessels, and then, when the neck wound is healed, dealing with the tongue. In this case the lymph is flowing from the cancer, and is going by roundabout routes, the limits of which we do not know, to the same side or to the opposite side of the neck; at the same time the collateral circulation is opened up, and instead of a blood supply the anatomical relations of which are well understood, we have one which is unknown, but is just as free. I merely state this as a common-sense view to take of the matter, and one which I now always follow, though I am well aware that many surgeons reverse the process, and most of the cases operated upon in the Mayo Clinic between the years 1910 and 1922 had the glands removed first.

#### *The Anaesthetic.*

This is a most important subject, and must be dealt with fully. A good anaesthetist is as important as a good surgeon; and by a good anaesthetist I do not mean one who anaesthetizes so that the patient can leave the operating table alive, but one who acts for the ultimate good of the patient.

There are four methods of anaesthetizing, all of which I have used.

First, there is the ordinary way of anaesthetizing by the mouth, at first by means of a mask, followed by some such apparatus as Junker's. This method has almost completely gone out of use; there was far too great a risk of the suction of blood and mucus into the upper bronchial passages, and consequent pneumonia. This method, however, is still used and even advocated by some.

There is the method by tracheotomy and the plugging of the pharynx—an excellent method, but a severe procedure, as the tracheotomy takes some time to perform, the wound does not heal at once, and there is an added risk of sepsis; still it is a great step in advance. The patient, however, is deprived of the ability to cough and clear his pharynx for some days after the operation.

Then there is laryngotomy. A small opening is made through the crico-thyroid membrane and a narrow tube thrust into the larynx, and the anaesthetic given through that, the pharynx being plugged. A small, flat laryngotomy tube is used or a bivalve tracheotomy tube; the opening takes only two or three minutes to perform. A small transverse incision is made and the membrane stabbed so that there is only a small hole, into which the tube fits so tightly that there is no bleeding. The tube is removed when the operation is finished; the sides of the wound come together, no air escapes, no emphysema occurs, and coughing is at once restored to the patient. This is by far the best of the methods used at the present day.

Lastly, there is the method of intratracheal delivery of the anaesthetic. This seemingly has very great advantages,

but they are more apparent than real. It gives a very nice quiet anaesthetic, but continual swabbing of the throat is necessary. It must be remembered, too, that as the entrance to the glottis is narrowed by the tube, the force with which material can be sucked in is proportionately increased, and there is a liability that pneumonia will follow. Also it is not always easy to introduce a tube into the larynx. Anaesthetists will say that it can be done with a mirror, and the tube not contaminated in any way from the ulcer. That may be so, but my experience has been that when the patient has arrived upon the table with the tube in place there are often evidences that it has not been altogether plain sailing, and, besides a considerable loss of time, I have frequently found that there was free bleeding from the ulcer. Pulling, tearing, or massaging of the ulcer is the last thing that is desired.

I share the opinion expressed by Trotter in this matter—that where there is a fungating mass in the mouth laryngotomy is the best procedure. Much time may be lost in attempting to pass the tube, during which the breathing may be seriously embarrassed, and an additional strain of unknown weight added to the seriousness of the operation. Be it remembered that most of these patients are old men, and any additional heart strain is to be avoided.

About the same time that Trotter expressed this opinion Rupert Jones published his experience of anaesthesia by this method. Two tongue cases were included. In the first, a man of 52, the tube was passed without difficulty; four days later the patient developed signs of pneumonia at the right base and died in a week. In the second, a man of 55, "intubation was repeatedly tried for thirty minutes" without success; laryngotomy was then performed. The patient died suddenly of heart failure twenty-eight hours later. A thirty minutes' struggle is hardly a happy preliminary to a serious operation, and probably contributed materially to the sequel. Trotter carefully limits his remarks to fungating tumours of the tongue, and excludes small warty or superficial growths where ulceration is absent or slight. I go further and hold that intratracheal anaesthesia for all serious intrabuccal operations upon the tongue is much inferior to laryngotomy from the surgeon's and from the patient's point of view; and I have had a large experience of both forms given by such excellent exponents as Dr. Chaldecott and Dr. Matthews. I therefore repeat that for the ultimate good of the patient the anaesthetic should be given by a laryngotomy tube; there should be no preliminary ligation of the lingual artery, and the neck should be left untouched till a later date and then dealt with as thoroughly as possible.

Wheeler<sup>1</sup> strongly recommends rectal anaesthesia, and states: "It is the method *par excellence* for excisions of the tongue or jaw and for the removal of goitre or glands in the neck." Its advantages are not quite obvious, and the pharynx cannot be plugged; but I have had no experience of the method and cannot judge.

There is another important point in the anaesthetic which it behoves the surgeon to inquire into. We know that the number of deaths upon the table is greater with chloroform than with ether. I am certain, however, that if the deaths were taken for fourteen days from the commencement of the operation the figures would be reversed, and the ether deaths would exceed those of chloroform in a most decided manner. The older the patients operated upon the more pronounced will this be.

The risk of death upon the table has, in my opinion, been allowed too great an influence in the matter of anaesthetics. The irritation of the ether is very marked in some people; we recognize this, and now in every case give atropine to counteract its action. Nature intended us to breathe through our noses and provides a large surface of epithelium to warm the air breathed, so that cold air shall not find its way into the lungs. Ether, being a vaporable fluid, becomes cold, and if delivered direct into the lungs through the opening in the trachea, larynx, or by the intratracheal tube, must be a most potent factor in the fatalities which ensue. The ether must be warmed, and if the operation is prolonged additional hot water must be added to the apparatus; unless pre-

cautions are taken, at the end of the operation it will be found that the water is cold and useless for the purpose of warming the vapour.

If a preliminary injection of morphine be given it should be a small dose. Hewitt has emphasized this; he had two or three fatalities, which were, he writes, "in my opinion, partly, if not chiefly, due to pneumonia excited by the passage of blood into bronchi rendered insensitive by morphine. The profession has not, I think, fully realized the importance of a rapid return of the coughing and swallowing reflexes after operation of this character."

With this opinion I cordially agree.

#### *Partial or Unilateral Excision.*

The patient being anaesthetized through a laryngotomy tube and the mouth gagged widely open, a stout silk ligature is placed through the anterior part of the tongue on each side. If the growth is far back it is an advantage to place one through the tongue behind the growth, as pulling on this will bring the back part of the organ much better into view. The pharynx is then plugged by a marine sponge to which a string is attached, which hangs out of the mouth.

The tongue being steadied, an incision is made through the mucous membrane suitable for the removal of the particular growth. In making this incision it should be remembered that a carcinoma does not spread laterally along the mucous membrane but along the lymphatics deeply into the substance of the tongue. There is no need, therefore, to remove the mucous membrane widely, and much more can be left to cover the raw surface of the mouth than is usually done. I do not for a moment wish you to think that the growth should be encroached upon: a full three-quarters of an inch should be left round the growth, but in a growth at the middle or behind the middle of the tongue it is unnecessary to remove the tip or mucous membrane of the under surface of the tongue.

The mucous membrane having been divided the two halves of the tongue can be separated; the mid-line should be closely inspected to see if there is any sign of the growth penetrating to the centre of the tongue. The tongue is then elevated and the origin of the genio-hyo-glossus muscle separated from the genial tubercle on the affected side. The stylo-glossus muscle in the anterior pillar of the fauces is divided.

On pulling the tongue upwards and to the opposite side the hyo-glossus muscle will be placed on the stretch. A director is inserted under this muscle, which is divided, exposing the lingual artery for the whole length of its second part. A ligature can be passed round it with an aneurysm needle, or the vessel may be caught with forceps, divided, and ligated. It should be ligated at once; if forceps are left on they are in the way and are apt to tear off or become loose, and the vessel may then bleed. This is the method of dealing with the vessel devised many years ago by Charles Cathcart. When the vessel has been secured some snips may be made into the tongue just where it has been caught to avoid injuring the vessel later. This is a better method of securing the lingual artery than snipping the tongue through in the hope of recognizing the vessel before it is out. The tongue can now be pulled further out of the mouth. By pulling on the back silk suture the hind part of the tongue can be better displayed. With snips of the scissors the tongue is now divided transversely well behind the growth. The face of the section should be closely inspected to make sure that infiltration has not reached it. Some twigs from the dorsalis linguae vessels may need to be secured. The tongue should now be turned round so that the tip is sutured to the base and the mucous membrane of the mouth stitched up as well as possible so as to diminish the raw area left. In many cases of partial excision, if thought has been given to this matter there is practically no raw area left, and the comfort of the patient is enormously increased; healing should be complete in most cases in ten days. The plugging is removed from the pharynx and the laryngotomy tube withdrawn, when the patient will at once breathe through the natural channel. A small dressing is applied to the neck, and the patient is then removed to bed. The operation is nearly as bloodless as when the lingual artery has been secured in the neck.

In complete excisions, where the whole of the tongue has been removed, the lingual artery is dealt with first on one side and then on the other.

If the tongue is divided very far back a silk suture should be placed through the glosso-epiglottidean fold and left hanging out of the mouth to draw forward the hyoid bone if necessary. It can usually be removed within twenty-four hours. The oozing can be stopped by applying a hot sponge to the raw surface. The tongue having been removed, the mucous membrane is sewn up, covering the floor of the mouth, part of the mucous membrane of the anterior pillars of the fauces being used for this purpose.

Some surgeons have advocated splitting the tongue and removing half at a time. Removal of the whole tongue, however, means that both halves are infiltrated, and longitudinal division means that infected or suspicious tissue must be cut through. This is a bad practice, as cancer cells may escape during the operation and may cause a local recurrence later.

#### *Treatment of the Stump.*

If the flaps have been cut with foresight and precision and the mucous membrane has been sewn up carefully, it is surprising what a small raw area need be left. What there is can be painted with warm friars' balsam; there is no advantage in adding iodoform to this. Swallowing is much less painful where there is only a small raw area. No dressing whatever need be applied, as it only distresses the patient to have foreign substance, gauze of all things, in the mouth. The stitch in the back of the stump is fastened to the cheek by a strip of plaster.

#### *After-treatment.*

Good after-treatment adds much to the comfort of the patient. The patient is returned to bed and laid upon his side with the head low, so that all mucus runs from the mouth on to a soft towel laid under the cheek. The nurse should be told to wipe away mucus from the lips, but on no account to insert anything into the mouth, or she may tear the sutured mucous membrane. Morphine should be withheld so that the patient returns to consciousness as soon as possible and is able to cough. A continual rectal saline can be given through a fine catheter without disturbing the patient. To this may be added brandy, bromide, chloral, and glucose, as thought necessary.

As soon as the patient regains consciousness sufficiently he should be propped up in bed with pillows. He is then taught to wash out his mouth himself whenever he feels inclined. For this a douche can be suspended near the head of the bed a few inches above the level of his mouth. He takes the tube, places it in his mouth, and allows the fluid to run in while he bends his head over a basin held by the nurse. He regulates the flow by pinching the tube. The patient much prefers to do this rather than have it done for him, as he can direct the stream where he wants it. The best fluid he can use is warm potassium permanganate, or warm 1 in 80 carbolic lotion. He will find these most comforting, and will probably use them frequently.

As a rule the patient can swallow the next day, and can be fed by the feeding cup and tube, which he has already accustomed himself to use previous to the operation. If there is any difficulty, he can be fed by passing a small, well oiled catheter a little way down into his oesophagus and allowing small quantities to run in slowly. Should any regurgitation or coughing take place the feeding cup or funnel should at once be lowered. The patient will probably prefer to feed himself.

A little water should be run in first to test that all is well; a little more can be run in to clear the tube before withdrawing it. In a few days the patient will be able to swallow quite well himself.

It is hardly necessary to add that all fluids used should be sterilized by boiling before use. A patient who cannot be fed in this way must be placed upon rectal enemata, upon which he may subsist for some days, until swallowing has become easy.

Time does not allow me to say much in connexion with the dissection of the neck. This, however, is just as important as the removal of the tongue. To be successful the

dissection of the neck should remove the whole of the gland-bearing fascia, both high up, far back, and low down. The best results seem to be gained by a block dissection starting from under the chin and extending backwards to the sternomastoid muscle, which must be removed in its greater part, together with the internal jugular vein. The dissection should extend back into the posterior triangles of the neck. Especially is it important to remove the glands high up under the parotid, a portion of which gland can also be removed. Better access can be obtained to this region by sawing off the angle of the jaw. The spinal accessory nerve has to be sacrificed in most cases, as it is surrounded by glands which cannot be separated from each other without the danger of the escape of their contents. No glands must be cut into, torn, or even squeezed, for fear of the escape of cancer cells.

This may seem an heroic procedure, and unnecessary in many cases, but only a careful examination later will show whether these glands have already become infected.

II.—**SIR WILLIAM MILLIGAN, M.D.**,  
Consulting Aurist and Laryngologist to the Manchester Royal Infirmary and to the Manchester Ear Hospital; Surgeon-Laryngologist to the Manchester Radium Institution.

### TREATMENT OF CARCINOMA OF THE TONGUE BY RADIO-DIATHERMY.

My share in to-day's discussion will be limited to experiences gained in the treatment of carcinoma of the tongue by means of radium, diathermy, and a combination of both methods—namely, radio-diathermy.

Every surgeon will, I think, admit that the purely surgical treatment of cancer of the tongue leaves much to be desired, that the results are in general most disappointing. With radio-active treatment and with diathermy much the same tale has to be told, notwithstanding the fact that considerable relief to the more distressing symptoms is obtained and life prolonged in comparative comfort in many cases for somewhat surprisingly long periods as the result of the destruction of the primary growth.

To my mind the supreme factor in the successful treatment of cancer is time. Cancer when seen early is a local disease capable in many cases of eradication and cure; when seen late, as unfortunately it most frequently is, dissemination to adjoining lymphatic glands has already taken place and varying degrees of toxæmia are present. The cases referred to the radiologist are almost without exception those considered inoperable by the surgeon, and are therefore the worst type of material to work upon. Notwithstanding this fact, the insertion of radium in suitable doses, with or without the destruction of the primary growth by diathermy, affords at times complete freedom from symptoms often for years, and great comfort by relieving pain, by preventing hæmorrhage, and by diminishing dysphagia.

For these reasons few cases are refused one or other form of treatment at the Manchester Radium Institute, even when the ultimate outlook is most unfavourable. "Hope springs eternal in the human breast," and experience has shown that a mitigation of the most distressing symptoms is of the greatest moment to the patient.

In almost all the tongue carcinomata dealt with the histological structure, as proved by microscopic section, is found to be that of a squamous-celled epithelioma—unfortunately the most resistant type of growth with which the radiologist is called upon to deal. Columnar-celled carcinomata are occasionally met with and prove somewhat more amenable to the influence of gamma radiations than the squamous-celled type.

The problems which have to be faced in the treatment of cancer of the tongue are:

1. Is operation a practical problem?
2. If it is, what is the best method of dealing with the primary growth?
3. Should the primary growth be removed prior to or subsequent to removal of the infected glands, or should growth and glands be removed at one and the same time?

4. Is it advisable or necessary to perform a preliminary ligation of the external carotid artery or of the lingual artery?

5. Has removal of the growth by the diathermy knife advantages as compared with ordinary surgical procedures?

6. Should insertion of radium into the growth be accompanied by radiation from the surface?

7. What are the advantages, if any, of combining radium and diathermy in the treatment of these cases?

Unfortunately many cases coming under review are obviously too advanced to permit of any reasonable possibility of successful surgical removal, partly from fixation of the tongue, from extension of the growth to adjacent areas of buccal, faucial, or tonsillar mucosa, and from the extensive lymphatic infection of one or both sides of the neck.

When surgical intervention is deemed admissible—and this undoubtedly varies with the mentality of the operator—it is, in my judgement, the proper course to adopt, and should be carried out on virgin soil as it were, without any previous irradiation, which, however serviceable as a post-operative procedure, only complicates successful surgical removal of the growth.

To effect an adequately free excision of certain tongue cancers with the knife is frequently impracticable, and it is just in such cases where the diathermy knife proves so useful, the tissues being slowly coagulated and a bloodless removal effected, bearing always in mind, however, that the occurrence of subsequent deformity must for the time being be ignored, the aim and object being to remove the growth in its entirety. Difficulties do not arise, however, so much with the removal of the primary growth as with the removal of the extensive secondary glandular deposits so frequently met with.

The lymphatic drainage from the tongue, largely submucous but partly intramuscular, runs in four well defined streams: (1) from the apex of the tongue, (2) from its sides, (3) from its median surface, and (4) from its base. The apical lymphatics drain into the submental and inferior cervical glands; those from its lateral surfaces into the submaxillary glands situated within and around the submaxillary salivary gland, and into the superior cervical and carotid glands; those from the median surface into the submaxillary glands; and those from its base into the superior deep cervical glands. It is also essential to note that lymphatic vessels cross the middle line of the tongue and drain into cervical glands on the side opposite to that on which the malignant growth or ulcer is situated. The problem of dealing efficiently with such a wide lymphatic field by ordinary surgical measures is thus a serious problem, at times so serious as to be impracticable. In such cases drenching the tissues with gamma radiations, either by the insertion of tubes or needles into the glands or by external radiation, opens up certain possibilities.

The insertion of suitably screened or unscreened tubes is undoubtedly more effective than external radiation. Where a sufficient quantity of radium is not at hand or obtainable, multiple puncture with a diathermy needle has at times proved serviceable.

Whether the primary growth should be treated first and glandular deposits second, or vice versa, is a moot point. My own preference is to attack the primary growth in the first instance, either by insertion of radium tubes screened or unscreened, or by means of diathermy button-shaped electrodes, or by excision with the diathermic cautery knife. I regard the glandular invasion as Nature's first defensive barrier, and consider that it acts as a filter bed of some importance during the period of temporary local disturbance which follows the removal or destruction of the primary growth. After the lapse of ten days or so a free dissection of the submaxillary and cervical triangles on the affected side should be undertaken, upon both sides if the disease is extensive. The radiation of the lymphatic tracts intervening between the primary growth and the secondary nodal deposits will depend upon the view held as to the method of dissemination of the cancer cell—whether it be the result of permeation or of embolic transmission. If the former view is held, the course of the lymphatic tributaries should be thoroughly irradiated, preferably by the insertion of tubes containing radium element or emanation along the course of their main channels or by external radiation from suitably disposed

## CARCINOMA OF THE TONGUE.

applicators. If, on the other hand, the embolic theory of transmission be accepted, then free surgical removal of all infected and non-infected glands is imperative, followed, if thought advisable, by surface radiation. The treatment of secondary deposits presents even greater difficulties than the treatment of the primary lesion, and ultimate success will be found to hinge largely upon the efficiency with which the infected lymph nodes and their tributaries have been removed or radiated. An important point to note in cases of cancer of the tongue is that lymphatic extension beyond the submaxillary and cervical triangles is rare.

The placing of enlarged lymphatic nodes containing radium over masses of superficial glands is not only an uncertain but also an unsatisfactory method of treatment, owing to the tolerance of the skin, which varies within such wide limits. The burying of tubes in the substance of glandular deposits in such a way as to form a barrage and secure efficient cross-fire is attended at times by shrinkage and disappearance of obviously enlarged nodes—rarely, however, by their complete disappearance, microscopic deposits even adopted. Unfortunately, in the substance of the hyoglossus and genio-hyo-glossus muscles, and possibly even cells in palpable glands in the substance of the hyoglossus and genio-hyo-glossus muscles, are not directly influenced, and form lymphatic tributaries, are not directly influenced, and form foci for ultimate recurrence. Whenever it is a practical proposition the glandular field should, in my opinion, be attacked surgically, either by ordinary dissection or by block dissection, followed by the burial of screened radium tubes in the course of the lymphatic stream, and later on by surface radiation. It is essential not only to attack the main army but also to annihilate the outposts.

The primary lesion in the tongue may be treated by means of applicators, screened tubes, or unscreened tubes containing radium or its emanation. The use of applicators for any length of time is obviously impracticable owing to the difficulty of retaining them *in situ*, and is, therefore, a method which need not be seriously entertained. Screened tubes may be buried in the growth and retained for periods of dosage. Owing to the screen absorbing all the alpha rays the therapeutic action is obtained from the beta and gamma radiations. The beta rays, however, being more local in their reaction than the gamma rays, are apt to produce necrosis, followed by sepsis, if retained for more than forty-eight hours, so that in practice it is advisable to cut off these rays by employing platinum-screened tubes with a thickness of 0.5 mm. containing 8 to 10 millicuries of emanation—equal to 8 to 10 mg. of radium element. The main objection to employing screened tubes in a mobile organ such as the tongue is that it is almost impossible to keep them accurately in *situ* for any length of time, and also on account of the risk of necrosis and implanting sepsis. For this reason we have recently been implanting into the substance of the growth large numbers of "seeds," containing emanation, leaving them to become encapsulated or to slough out—the object aimed at being to devitalize the malignant cells and induce a state of fibrosis. These "seeds" or capillary tubes are from 3 to 6 mm. in length and from 1 to 2 mm. in thickness, and contain a dose of from 0.3 to 0.6 millicurie of emanation.

For effective therapy the lingual artery should invariably be ligated and the growth exposed so far as it is possible to do so, in order to permit of its being handled for the accurate implantation of the seeds in parallel series. The cutting off of the main blood supply frees the patient from the risks of haemorrhage and does not interfere with the therapeutic action of the seeds into the substance of the growth should follow a definite plan, parallel rows 1 cm. apart being inserted by means of a specially devised needle, those seeds implanted in the growth itself having a greater radio-activity than those inserted at its periphery.

The cases which in private practice come within the purview of the laryngologist are as a rule those cases of malignant disease which primarily attack the faucial, palatal, or buccal mucosa, and which later on spread to the tongue itself. In carcinoma of the larynx we differentiate cases as intrinsic and extrinsic—those which attack the interior of the laryngeal box and those which

spread beyond its confines. In the former the prognosis is relatively good, owing largely to the late involvement of the lymphatic plexuses; in the latter, on the other hand, owing to the early involvement of lymphatic tracts, it is very bad. So in the tongue—in growths limited to the tongue (intrinsic cases)—early surgical removal of the affected whole or half of the organ, if carried right down to the hyoid bone, yields reasonably good results; if, on the other hand, tissues extrinsic to the tongue are involved, the prognosis is essentially grave whatever form of treatment is adopted. In such cases excision of the affected area with the diathermic cautery knife presents many advantages. In the first place, if the operation is done with deliberation there is little, if any, haemorrhage, the activity of the malignant cell is destroyed by coagulation, and owing to the sealing up of lymphatic tributaries the dissemination of the cancer cell is prevented. As a precautionary measure it is advisable to ligate the lingual or the external carotid artery. The current used should be from 1½ to 2 amperes, and should be increased from zero to full strength in about thirty seconds. When steaming takes place the current should be at once stopped, as at that moment the diathermic action ceases.

Another great advantage of diathermic excision is that it can be employed in the case of growths not readily accessible to ordinary cutting operations—for example, growths in the faucial region and posterior part of the tongue. The disadvantage of the method is that a slough forms, and the mouth becomes very septic. The slough separates, however, as a rule within ten to twenty days, during which time the lymph vessels have become obliterated, so that distant septic infection is rare and dissemination of the cancer cell prevented. When excision is not possible, a useful method is destruction of the primary growth by button- or spike-shaped electrodes, the depth of tissue destroyed by each application being equal to the square of the surface of the applicator employed. Very extensive destruction of tissue is therefore possible with diathermic treatment. Healing is remarkably rapid and the resulting scar tissue soft and pliable. Should considerable deformity ensue, some plastic operation may be subsequently performed, or a mechanical appliance be worn.

Diathermic treatment in conjunction with radium is particularly valuable. Where extensive ulceration is present, buried in the tissues. Where extensive ulceration is present, sepsis is largely eliminated as the result of sterilization of the tissues by the high frequency current and the risks of haemorrhage owing to an endarteritis obliterans following irradiation. My experience of these distressing cases leads me to state:

- (1) That whenever possible immediate surgical removal of the primary growth and of the lymphatic field draining the focus of infection should be carried out.
- (2) That when surgical intervention is deemed impracticable an attempt should be made to remove the growth with the diathermic knife or to destroy it by gradual coagulation with button- or spike-shaped electrodes.
- (3) That when removal of the growth is contraindicated the insertion of unscreened radium tubes into its substance should be carried out.
- (4) That combined treatment by means of diathermic coagulation and radium implantation affords at times gratifying results.
- (5) That in early cases the lymphatic field upon the affected side should be dealt with surgically; in advanced cases the lymphatic field upon both sides.
- (6) That irradiation of the lymphatic field should be an invariable post-operative procedure, preferably by the implantation of screened tubes, or alternately by surface application or x-ray therapy.
- (7) That no preliminary radiation should be employed if glandular deposits are to be removed by ordinary surgical procedures.
- (8) That the diathermic cautery knife presents many advantages as compared with the scalpel for the removal of a cancerous tongue.

Through the courtesy of my colleagues Drs. Burrows and Birkett, I am able to place before you the results of the treatment of 812 cases of cancer of the tongue and mucous membrane of the mouth treated between January, 1915,

and December, 1925. The methods of treatment adopted were as follows:

|  |     |           |
|--|-----|-----------|
| Superficial applicators in ...           | ... | 33 cases. |
| Screened tubes (24 hours or less) in ... | ... | 269 "     |
| Screened tubes (24-48 hours) in ...      | ... | 51 "      |
| Unscreened tubes in ...                  | ... | 249 "     |
| Unscreened tubes and diathermy in ...    | ... | 61 "      |
| Screened tubes and diathermy in ...      | ... | 11 "      |
| Screened and unscreened tubes in ...     | ... | 67 "      |
| Various combinations in ...              | ... | 15 "      |

Out of the 812 cases treated, only 51 can be regarded as successful. These 51 cases have been well for the following periods:

|                 |   |                  |    |
|-----------------|---|------------------|----|
| For 9 years ... | 1 | For 3 years ...  | 8  |
| " 8 years ...   | 1 | " 2 years ...    | 5  |
| " 5 years ...   | 2 | " 1 year ...     | 16 |
| " 4 years ...   | 5 | Under 1 year ... | 13 |

The 51 cases were treated as follows:

|   |     |    |
|---|-----|----|
| By superficial applications alone ...                                   | ... | 2  |
| By screened tubes buried in the lesion ...                              | ... | 6  |
| By screened tubes and diathermy ...                                     | ... | 2  |
| By unscreened tubes ...   | ... | 21 |
| By unscreened tubes and diathermy ...                                   | ... | 7  |
| By a combination of screened tubes, diathermy, and unscreened tubes ... | ... | 13 |

Unscreened tubes—in my opinion the method of the future—were therefore employed in 41 cases in which the primary lesion cleared up; of these 41 cases 35 have been well for over one year and 20 for two years or more.

The accompanying table of results is taken from the annual report of the Manchester Radium Institute for 1925, and is compiled by the radiologist, Dr. G. E. Birkett, to whom I am much indebted for assistance in the preparation of these notes. The results can certainly not be considered brilliant, but with the type of case dealt with—surgically inoperable—they show at least that alternative methods hold out hopes of relief and periods of freedom from the most urgent symptoms of the disease.

Finally, Mr. President, an apology is perhaps due from me as a laryngologist for intruding into the holy of holies—that is to say, into a purely Surgical Section. I do so, however, at the invitation of your secretaries in order that I may place before you an unvarnished tale of the experiences gained at the Manchester Radium Institute and in my own private practice in the treatment of carcinoma of the tongue with radium, with diathermy, and with a combination of both methods.

No one, however impassionately reviewing the results of the treatment of cancer of the tongue by purely surgical measures or by one or other of the accessory forms of treatment, can remain satisfied with the results as at present; nor will the results, in my judgement at least, ever be good until the public realize the importance of applying for assistance at a much earlier stage of the disease than is usual to-day. This implies on the part of the public a knowledge of the importance of the early signs and symptoms of malignant disease, knowledge which can only be obtained if the profession lends itself to what in my opinion is so much needed in this country—namely, an anticancer crusade.

#### GENERAL DISCUSSION.

Mr. W. S. DICKIE (Middlesbrough) wished to confine himself to cancer of the postero-lateral part of the tongue. These growths were very often tumours of the fauces which had extended to the tongue. They very often spread outwards to the jaw and backwards to the tonsil or upwards to the soft palate. The jaw-bone dominated the whole operative procedure. He regarded temporary resection as useless, because the bone was very early involved. In operating upon these cases he first paid attention to the hygiene of the mouth, but did not remove teeth—mouth-washes and wiping alone being used. The anaesthetic was administered through a laryngotomy tube. He removed the jaw from the canine fossa backwards, including the condyle, and thus gained free access to the side of the pharynx. He did not perform a block dissection of the neck, although he cleared out all the glands and connective tissue, the sterno-mastoid being left. This part of the operation was done first and the jaw then removed subperiosteally. He thought it sufficient to leave half an inch margin of uninfected tissue around the growth. During the last five years he had operated upon 17 patients with 4 deaths; 8 of them had had no recurrence up to date. Two cases were exhibited.

Mr. G. GORDON-TAYLOR (London) said that carcinoma of the tongue was a disease of neglect of mouth hygiene and of syphilis; it was not a disease of the wealthier classes. He was accustomed to operating upon these cases in three stages: block dissection of the neck on one side, removal of the tongue, and block dissection of the neck on the other side. He had recently changed his technique, and had begun taking out the tongue first and doing a block dissection of the neck second. He had been led to do this because of the high mortality which accompanied an efficient operation. In 69 cases in which a mouth dissection had been performed with a diathermy knife, with a double block dissection in nearly every case, the mortality was 48 per cent. Against this very serious death rate he was able to show 50 per cent. of the survivors alive and well up to five and a half years. He found that 90 per cent. of the deaths were due to bronchopneumonia, and the risk of this occurring was greater after the mouth than after the neck operation. Laryngotomy facilitated the administration of the anaesthetic and diminished the incidence of bronchopneumonia, but did not prevent it. Patients who died from this cause succumbed on the third day after the

## POST-OPERATIVE TREATMENT OF CANCER OF BREAST.

DEC. 11, 1926]

operation. He thought the complication was due to discharges trickling down the throat. He believed that the glands should always be removed on both sides of the neck. On the second side, if no enlarged glands were felt, however, only the upper part needed dissection. He never performed bilateral block dissection at one operation as the patients always died. In order to gain access to the mouth in difficult cases he was accustomed to remove the alveolar part of the jaw: this was much better than splitting the bone involvement, necessitating bone resections. He maintained that the prognosis was hopeless, since he could produce survivors in such cases up to five years and more. Although the primary mortality was very heavy, he did not take such a gloomy view of the outlook for these patients as many authorities, because he was able to establish a cure in about 50 per cent. of his survivors.

Mr. E. DEANESLY (Wolverhampton) said that the ultimate results of the purely surgical treatment of this disease were so discouraging that many surgeons would willingly hand them over to anyone who could cure them by any form of diathermy or radiation. Unfortunately, though it was not difficult to destroy the primary growth by such means, this was of little use unless the infected glands could also be destroyed or removed, and few radiologists claimed to be able to do this without a surgical operation on the neck. For the present, therefore, if the primary growth was surgically removable, from an anatomical point of view there seemed little advantage in diathermy, since the gland dissection was still necessary afterwards. But in certain situations where the growth involved the gums, the palate, or the tonsils, diathermy was the best means of dealing with it, the glands being removed by a subsequent block dissection. As regards the surgical treatment of removable cancer, and had employed agreed entirely with Mr. Fitzwilliams, removal of the same method for many years—namely, removal of the affected part of the tongue entirely through the mouth before any operation on the neck, the use of chloroform through a temporary laryngotomy with plugging of the pharynx, and the complete covering of the raw surface with mucous membrane; this operation to be followed by block dissection of the neck, each side at a separate operation. He thought that operations involving the division or excision of parts of the mandible were rarely worth doing.

Mr. STANFORD CAVE (London) said that in the surgery of cancer of the tongue and the treatment of cervical glands regional anaesthesia had proved a great advance. It diminished inhalation risks and gave perfect freedom in neck manipulation. The routine consisted in injecting a solution of 1 1/2 per cent. novocain near the lingual and inferior dental nerves and a cervical paravertebral block of the second, third, and fourth cervical nerves. By this method intraneural manipulations and dissection of the neck were accomplished painlessly. The unsatisfactory results of surgical treatment of lingual cancer led him to adopt the methods advocated by Professor Regaud in Paris and Professor Bayet in Brussels. He had substituted radium therapy for surgical removal in all cases of cancer of the tongue for the past two and a half years. Radium needles containing 0.6 mg. of the element and screened by 1/2 mm. of platinum were inserted around the growth in healthy tissue and left in position for five to seven days or even longer. Preliminary cleaning of the mouth was obtained by a biopsy was performed from radium necrosis was obtained lower and upper jaws by subperiosteal resection. If the cervical glands were enlarged but operable a Crile's dissection was performed: if the glands were not enlarged, or if enlarged and inoperable, surface application of large doses of radium by means of Columbia paste collars, giving the requisite distance from the skin, were made use of. Results were highly encouraging and surpassed anything offered by surgery. This applied only to the disappearance of the primary growth: no claim whatsoever as to cure could be made at this early stage.

Mr. D. C. L. FITZWILLIAMS (London) referred to the workers at the Curie Institute; their results were about 25 per cent. of five-year cures. They had abandoned unscreened tubes as being dangerous for insertion. For glands it was recognized that block dissection gave better results than radium alone, and external applicators were very largely used. He was surprised at the bad results from operation reported by Mr. Gordon-Taylor: he agreed that the majority of deaths would be reduced by withholding morphine, so as not to interfere with coughing, and by warming the anaesthetic. Sewing up the mucous membrane avoided the danger of a raw septic area, and the diathermy knife would be modified above all by not using the diathermy knife in those cases where sufficient margin could not be obtained by other means. Every thinking surgeon knew that the best instruments with which to divide tissues was a retrograde step. No other method produced so little damage. Haemorrhage in the modern operation was negligible. He advised very strongly against performing block dissections of both sides. There was seldom any necessity for this unless the glands were obviously affected on both sides, when, in his opinion, operation held out little or no hope of prolonging life. Block dissection should be performed on the affected side and the other side supervised each month or two months. The infection would be limited, as there was now no source from which malignant any affected glands could be easily and safely removed while small, provided they were not pinched, handled, or cut into, and ample time would be allowed to perform the second block dissection when it became necessary. Better results would be obtained by early diagnosis than by increasing the scope and range of operations.

Sir WILLIAM MILLIGAN, in reply, reminded the meeting that the cases of tongue carcinoma dealt with at the Manchester Radium Institute were cases deemed inoperable by ordinary surgical measures. He thought that there was ample room for an improvement even in the inoperable group of cases. No attempt was made to interfere with glands by any diathermic process; if the glands were operable, they were removed by ordinary surgical procedures. The radium technique was changed from time to time. He was not a slave to any one particular method, but it so happened in the table of statistics shown on the screen that 41 of the 51 more or less successful cases were treated with unscreened tubes. He was well aware that the pendulum had swung round to the employment of small doses in screened tubes for prolonged periods—a method which he also had employed for some considerable time past.

## POST-OPERATIVE TREATMENT OF CANCER OF THE BREAST.

BY  
H. W. CARSON, F.R.C.S.,  
Surgeon, Prince of Wales's General Hospital, London.

Cancer of the breast is one of the few cancers that becoming recognized at an earlier date; it is rare now to see the advanced cases which were common enough in the past. At the same time they are apparently increasing in frequency, and with the development of the knowledge of surgery in the profession it may often fall to the lot of a medical man to have to make himself responsible, if not for the actual operation, certainly for the post-operative treatment. It may be interesting therefore to mention a few practical points which may make the convalescence go more smoothly.

*Uniformity of Operation.*  
The operation is becoming standardized. Adopting the permeation theory of Sampson Handley, it is generally agreed that the operation should consist of the removal of the whole breast with a minimal sacrifice of skin, and a wide removal (a circle 10 inches in diameter centred on

and December, 1925. The methods of treatment adopted were as follows:

|  |           |
|--|-----------|
| Superficial applicators in ...           | 33 cases. |
| Screened tubes (24 hours or less) in ... | 269 "     |
| Screened tubes (24-48 hours) in ...      | 51 "      |
| Unscreened tubes in ...                  | 249 "     |
| Unscreened tubes and diathermy in ...    | 61 "      |
| Screened tubes and diathermy in ...      | 11 "      |
| Screened and unscreened tubes in ...     | 67 "      |
| Various combinations in ...              | 15 "      |

Out of the 812 cases treated, only 51 can be regarded as successful. These 51 cases have been well for the following periods:

|                 |   |                  |    |
|-----------------|---|------------------|----|
| For 9 years ... | 1 | For 3 years ...  | 8  |
| " 8 years ...   | 1 | " 2 years ...    | 5  |
| " 5 years ...   | 2 | " 1 year ...     | 16 |
| " 4 years ...   | 5 | Under 1 year ... | 13 |

The 51 cases were treated as follows:

|   |    |
|---|----|
| By superficial applications alone ...                                   | 2  |
| By screened tubes buried in the lesion ...                              | 6  |
| By screened tubes and diathermy ...                                     | 2  |
| By unscreened tubes ...   | 21 |
| By unscreened tubes and diathermy ...                                   | 7  |
| By a combination of screened tubes, diathermy, and unscreened tubes ... | 13 |

Unscreened tubes—in my opinion the method of the future—were therefore employed in 41 cases in which the primary lesion cleared up; of these 41 cases 35 have been well for over one year and 20 for two years or more.

*Details of Cases in which the Primary Lesion has been apparently Cured.*

|    | Site.              | Treatment.  | Meta-stases. | Sec-tion. | No. of Years Well. |

The accompanying table of results is taken from the annual report of the Manchester Radium Institute for 1925, and is compiled by the radiologist, Dr. G. E. Birkett, to whom I am much indebted for assistance in the preparation of these notes. The results can certainly not be considered brilliant, but with the type of case dealt with—surgically inoperable—they show at least that alternative methods hold out hopes of relief and periods of freedom from the most urgent symptoms of the disease.

Finally, Mr. President, an apology is perhaps due from me as a laryngologist for intruding into the holy of holies—that is to say, into a purely Surgical Section. I do so, however, at the invitation of your secretaries in order that I may place before you an unvarnished tale of the experiences gained at the Manchester Radium Institute and in my own private practice in the treatment of carcinoma of the tongue with radium, with diathermy, and with a combination of both methods.

No one, however impassionately reviewing the results of the treatment of cancer of the tongue by purely surgical measures or by one or other of the accessory forms of treatment, can remain satisfied with the results as at present; nor will the results, in my judgement at least, ever be good until the public realize the importance of applying for assistance at a much earlier stage of the disease than is usual to-day. This implies on the part of the public a knowledge of the importance of the early signs and symptoms of malignant disease, knowledge which can only be obtained if the profession lends itself to what in my opinion is so much needed in this country—namely, an anticancer crusade.

#### GENERAL DISCUSSION.

Mr. W. S. DICKIE (Middlesbrough) wished to confine himself to cancer of the postero-lateral part of the tongue. These growths were very often tumours of the fauces which had extended to the tongue. They very often spread outwards to the jaw and backwards to the tonsil or upwards to the soft palate. The jaw-bone dominated the whole operative procedure: He regarded temporary resection as useless, because the bone was very early involved. In operating upon these cases he first paid attention to the hygiene of the mouth, but did not remove teeth—mouth-washes and wiping alone being used. The anaesthetic was administered through a laryngotomy tube. He removed the jaw from the canine fossa backwards, including the condyle, and thus gained free access to the side of the pharynx. He did not perform a block dissection of the neck, although he cleared out all the glands and connective tissue, the sterno-mastoid being left. This part of the operation was done first and the jaw then removed subperiosteally. He thought it sufficient to leave half an inch margin of uninfected tissue around the growth. During the last five years he had operated upon 17 patients with 4 deaths; 8 of them had had no recurrence up to date. Two cases were exhibited.

Mr. G. GORDON-TAYLOR (London) said that carcinoma of the tongue was a disease of neglect of mouth hygiene and of syphilis; it was not a disease of the wealthier classes. He was accustomed to operating upon these cases in three stages: block dissection of the neck on one side, removal of the tongue, and block dissection of the neck on the other side. He had recently changed his technique, and had begun taking out the tongue first and doing a block dissection of the neck second. He had been led to do this because of the high mortality which accompanied an efficient operation. In 69 cases in which a mouth dissection had been performed with a diathermy knife, with a double block dissection in nearly every case, the mortality was 48 per cent. Against this very serious death rate he was able to show 50 per cent. of the survivors alive and well up to five and a half years. He found that 90 per cent. of the deaths were due to bronchopneumonia, and the risk of this occurring was greater after the mouth than after the neck operation. Laryngotomy facilitated the administration of the anaesthetic and diminished the incidence of bronchopneumonia, but did not prevent it. Patients who died from this cause succumbed on the third day after the

# POST-OPERATIVE TREATMENT OF CANCER OF BREAST.

[THE BRITISH MEDICAL JOURNAL] 1095

operation. He thought the complication was due to discharges trickling down the throat. He believed that the glands should always be removed on both sides of the neck. On the second side, if no enlarged glands were felt, however, only the upper part needed dissection. He never performed bilateral block dissection at one operation as the patients always died. In order to gain access to the alveolar part of the jaw; this was much better than splitting the mandible. In 30 to 40 per cent. of his cases there had been bone involvement, necessitating bone resections. He maintained that the presence of enlarged glands in the neck did not make the prognosis hopeless, since he could produce survivors in such cases up to five years and more. Although the primary mortality was very heavy, he did not take such a gloomy view of the outlook for these patients as many authorities, because he was able to establish a cure in about 50 per cent. of his survivors.

Mr. E. DEANESLY (Wolverhampton) said that the ultimate results of the purely surgical treatment of this disease were so discouraging that many surgeons would willingly hand them over to anyone who could cure them by any form of diathermy or radiation. Unfortunately, though it was not difficult to destroy the primary growth by such means, this was of little use unless the infected glands could also be destroyed or removed, and few radiologists claimed to be able to do this without a surgical operation on the neck. For the present, therefore, if the primary growth was surgically removable, from an anatomical point of view there seemed little advantage in diathermy, since the gland dissection was still necessary afterwards. But in certain situations where the growth involved the gums, the palate, or the tonsils, diathermy was the best means of dealing with it, the glands being removed by a subsequent block dissection. As regards the surgical treatment of removable cancer of the tongue he agreed entirely with Mr. Fitzwilliams, and had employed the same method for many years—namely, removal of the affected part of the tongue entirely through the mouth before any operation on the neck, the use of chloroform through a temporary laryngotomy with plugging of the pharynx, the exposure of the larger vessels before cutting them, and the complete covering of the raw surface with mucous membrane, this operation to be followed by block dissection of the neck, each side at a separate operation. He thought that operations involving the division or excision of parts of the mandible were rarely worth doing.

Mr. STANFORD CADE (London) said that in the surgery of cancer of the tongue and the treatment of cervical glands regional anaesthesia had proved a great advance. It diminished inhalation risks and gave perfect freedom in neck manipulation. The routine consisted in injecting a solution of 1/2 per cent. novocain near the lingual and inferior dental nerves and a cervical paravertebral block of the second, third, and fourth cervical nerves. By this method intrabuccal manipulations and dissection of the neck were accomplished painlessly. The unsatisfactory results of surgical treatment of lingual cancer led him to adopt the methods advocated by Professor Regaud in Paris and Professor Bayet in Brussels. He had substituted radium therapy for surgical removal in all cases of cancer of the tongue for the past two and a half years. Radium needles containing 0.6 mg. of the element and screened by 1/2 mm. of platinum were inserted around the growth in healthy tissue and left in position for five to seven days or even longer. Preliminary cleaning of the mouth was essential. A biopsy was performed in every case. Protection of the lower and upper jaws from radium necrosis was obtained either with lead or by subperiosteal resection. If the cervical glands were enlarged but operable a Crile's dissection was performed: if the glands were not enlarged, or if enlarged and inoperable, surface application of large doses of radium by means of Columbia paste collars, giving the requisite distance from the skin, were made use of. Results were highly encouraging and surpassed anything offered by surgery. This applied only to the disappearance of the primary growth; no claim whatsoever as to cure could be made at this early stage.

Mr. D. C. L. FITZWILLIAMS (London) referred to the workers at the Curie Institute; their results were about 25 per cent. of five-year cures. They had abandoned unscreened tubes as being dangerous for insertion. For glands it was recognized that block dissection gave better results than radium alone, and external applicators were very largely used. He was surprised at the bad results from operation reported by Mr. Gordon-Taylor; he agreed that the majority of deaths were from bronchopneumonia. He believed that this death rate would be reduced by withholding morphine, so as not to interfere with coughing, and by warming the anaesthetic. Sewing up the mucous membrane avoided the danger of a raw septic area, and the mortality would be modified above all by not using the diathermy knife. The speaker now only used the diathermy knife in those cases where sufficient margin could not be obtained by other means. Diathermy, though fashionable, was a retrograde step. Every thinking surgeon knew that the best instruments with which to divide tissues were the knife and scissors; no other method produced so little damage. Haemorrhage in the modern operation was negligible. He advised very strongly against performing block dissections of both sides. There was seldom any necessity for this unless the glands were obviously held out on both sides, when, in his opinion, operation should be performed on the affected side and the other side should be left alone. If the patient was kept under supervision each month or two months, it would be seen at once if any affected glands appeared. The infection would be limited, as there was now no source from which malignant emboli could come. Infected glands could be easily and safely removed while small, provided they were not pinched, handled, or cut into, and ample time would be allowed to perform the second block dissection when it became necessary. Better results would be obtained by early diagnosis than by increasing the scope and range of operations.

Sir WILLIAM MILLIGAN, in reply, reminded the meeting that the cases of tongue carcinoma dealt with at the Manchester Radium Institute were cases deemed inoperable by ordinary surgical measures. He thought that there was ample room for an improvement even in the inoperable group of cases. No attempt was made to interfere with glands by any diathermic process; if the glands were operable, they were removed by ordinary surgical procedures. The radium technique was changed from time to time. He was not a slave to any one particular method, but it so happened in the table of statistics shown on the screen that 41 of the 51 more or less successful cases were treated with unscreened tubes. He was well aware that the pendulum had swung round to the employment of small doses in screened tubes for prolonged periods—a method which he also had employed for some considerable time past.

## POST-OPERATIVE TREATMENT OF CANCER OF THE BREAST.

H. W. CARSON, F.R.C.S.,  
Surgeon, Prince of Wales's General Hospital, London.

CANCER of the breast is one of the few cancers that are becoming recognized at an earlier date; it is rare now to see the advanced cases which were common enough in the past. At the same time they are apparently increasing in frequency, and with the development of the knowledge of surgery in the profession it may often fall to the lot of a medical man to have to make himself responsible, if not for the actual operation, certainly for the post-operative treatment. It may be interesting therefore to mention a few practical points which may make the convalescence go more smoothly.

### Uniformity of Operation.

The operation is becoming standardized. Adopting the permeation theory of Sampson Handley, it is generally agreed that the operation should consist of the removal of the whole breast with a minimal sacrifice of skin, and a wide removal (a circle 10 inches in diameter centred on

the growth) of deep fascia, including the sheath of the upper rectus abdominis on the affected side. The whole of the pectoralis major muscle, except its clavicular origin—even that in some cases—and the pectoralis minor are removed, and the axilla is dissected downwards from the costo-coracoid membrane, which is removed. The supra-clavicular fossa is not dissected as a routine.

There are certain points in the performance of the operation which help in the convalescence.

1. The removal of only the necessary amount of skin with the wide undercutting required to remove the deep fascia allows the incision to be sutured without tension in most cases. This has an important bearing on shock, pain, the healing of the wound, and chest complications.

2. The incision is designed so that the scar is kept out of the axilla. This is of importance for subsequent free movement.

3. The most minute care is taken to reduce loss of blood. Nearly all the bleeding comes from the anterior perforating arteries in removing the pectoralis major, and a capable assistant will pick up many of these vessels before they are cut.

4. Shock is minimized by protecting all raw areas which are not actually being worked on, by towels wrung out in hot saline solution.

5. Delicate quick work without tearing or rough handling reduces shock and promotes healing by first intention.

#### *Immediate Post-operative Complications.*

Shock is not often seen in these cases, but occurs sometimes three to four hours after return to bed. I always anticipate this possibility and institute the following treatment as a routine. Immediately after operation 1 pint of saline solution with 5 per cent. glucose is given by the rectum. This is repeated in four hours, and at the same time the patient is wrapped up in two blankets and placed under a cradle, to which is fastened an ordinary incandescent lamp. This lamp is kept alight for half an hour, then there is one hour's intermission, and it is turned on again for another half-hour. A hypodermic injection of morphine is given if the patient is restless or in pain, and is generally needed, though it is not often repeated.

Pain is not severe after the first night, and is excited later on only by the early dressings which inevitably lead to movements of the arm or body. All patients complain about the arm in whatever position it is placed.

Chest complications are rare, and are best avoided by careful preparation, especially of the upper air passages, by closing the wound without tension, and by avoiding tight bandaging. The patient is made to sit up in bed after the first twenty-four hours or less.

A few cases of paralysis of the upper arm have been recorded; I have had two in my own practice. The paralysis always affects the biceps, and is, I think, due to pressure on the outer cord of the brachial plexus, by excessive extension of the arm during the operation.

#### *Position of the Patient.*

The patient is supported by a wedge formation of pillows in a sitting position, and the elbow, forearm, and hand are carefully packed up with pillows. My practice is to keep the arm at right angles to the body from the first; it may be sufficient to support it on pillows, taking care to support the forearm and hand also, or it may be necessary to tie it to the head of the bed for the first few hours. I am convinced that the right-angled position is less painful, does not increase oozing, and makes the early attempts at mobility less difficult and painful.

#### *Drainage.*

Fluid appears in three areas: (1) in the axilla, (2) in the suprapectoral space, and (3) in the upper end of the rectus abdominis; the first and last collect blood, the second serum. Some surgeons drain the wound by four or five tubes introduced through stab wounds in the posterior flap. I do not consider this necessary, but I drain the axilla by a tube passed through a stab wound in the axilla flap, which I place as far back as I can, and I rely upon evacuation of the other collections by means of dressing forceps passed between the stitches of the main wound. I believe that the

recognition and evacuation of these collections makes all the difference in the primary healing of the wound. This is by first intention as a rule. Occasionally necrosis of the edge of the axillary flap occurs, but rarely any other complication. The old idea that suppuration made recurrence less likely was very comforting, but there is very little evidence to support it. It is most important that the scar should not be allowed to become adherent to the chest wall, and it should be gently moved from the first.

#### *Movements of the Arm.*

The subsequent comfort of the patient and her value to the community depend much upon free mobility of the arm. Removal of the pectorals makes astonishingly little difference to the value of the arm, at any rate for ordinary pursuits, but limitation of shoulder movements is a real handicap, and is always associated with pain. My practice is to do the first dressing on the second day, and at each subsequent dressing passive movements, abduction, and forward and backward swinging movements are practised. Active shoulder movements are started at the end of the first week, but from the first the patient is allowed to flex and extend the elbow. At the end of the second week the patient should be able to raise her arm unaided to the side of her head. By this time she is allowed to get up. I am no advocate of early rising after this severe operation.

Swelling of the arm may occur as a later complication. I believe this to be due to pressure on the axillary vein by adhesions in the axilla, and that it is best prevented by strict asepsis and early movement. If it occurs it must be treated by massage and shoulder movements, but if it persists the axilla should be reopened and the vein freed. I have not had any lasting success with the Kondoleon or other operation.

#### *Radiation.*

It is difficult to obtain evidence for or against the routine use of x rays as a prophylactic against recurrence. I have had no personal experience of rapid or widespread recurrences which have been reported by some observers after the use of x rays, and I have had considerable experience of the value of radium and x rays in the treatment of recurrences. My own feeling is against its prophylactic use, but I will admit that I am ready and willing to be convinced of its value.

#### *Keeping under Observation.*

I make it a rule that all my patients shall attend for my inspection once a month for the first year, once in three months in the second year, and twice in the third year. Routine inspection in this way has allowed me to discover the occurrence of supraclavicular gland involvement in several cases before the patient was aware of it, and a timely operation is easy and curative. An x-ray examination of the mediastinum is also of value as an assurance of the absence of complications.

#### *Summary.*

In breast cancer operations success depends upon several factors:

1. The correct planning of the operation by the surgeon, so as to assure primary union and free movement after a thorough removal.

2. The skill of the surgeon's assistant in controlling haemorrhage and avoiding exposure during operation.

3. Skilful nursing to prevent shock and promote comfort.

4. Early movement to prevent fixation of the scar and limitation of shoulder movements.

5. Careful examination and re-examination at stated intervals for at least three years.

#### **DISCUSSION.**

Professor R. E. KELLY (Liverpool) recommended Kocher's incision for the removal of carcinoma of the breast and excision of a wider area of skin than Mr. Carson had depicted. He had found that recurrences, when they occurred locally, were not necessarily in the margins of the incision, but 1 to 1½ inches away from it.

Mr. D. C. L. FITZWILLIAMS (London) thought that no incision for removal of the breast need extend to the arm. The line of the vessels was from the middle of the clavicle

to the inner side of the arm. No incision need pass beyond the vessels along the inner side of which lay the glands of the axilla. He always made a plastic flap, which he used to fill in the gap left by the large amount of skin he took away. The easiest way of undermining the skin was, not to reflect it in the ordinary way, but to thrust a 6-inch amputating knife under the skin, and cut parallel with the skin. The flap could thus be cut with great rapidity and accuracy, especially in a fat patient.

Mr. GARNETT WRIGHT (Manchester) considered the kind of incision unimportant provided no scar was left in the axilla. He thought some skin should be taken away and that a continuous suture was far better than uninterrupted tension stitches, since it was less liable to cause necrosis. He regarded the position in which the arm was placed after

operation as unimportant, but it should not be fixed. Active, not passive, movements were necessary, as they prevented adhesions of the scar to the chest wall.

Mr. C. GORDON-TAYLOR (London) said that he had made an extensive trial of post-operative x-ray treatment. He had found that the prognosis was rendered worse and had therefore abandoned it. Recently he had been performing the operation with the diathermy knife, a method which led to less loss of blood. He regarded the operation on the breast as always a very serious one. He had had two cases of traction palsy in carcinoma of the breast.

Mr. GEORGE SIMPSON (Liverpool) thought x-ray treatment after operation a very valuable addition. It was continued for six to twelve months, and he was very satisfied with the results.

## DISLOCATION OF OUTER END OF CLAVICLE.

BY

A. B. MITCHELL, O.B.E., B.Ch., F.R.C.S.I.,

Surgeon, Royal Victoria Hospital, Belfast.

This injury is not very common. The deformity is easily reduced but difficult to keep reduced. Partial recurrence always follows the ordinary method of treatment. I have never seen a patient who could play football after this

7. The ligature is now tightened and tied on the upper surface of the acromion. The effect of this is to pull the clavicle first downwards and then outwards, and to hold it firmly apposed to the acromion.

8. The periosteum around the edges of the new joint is sutured by fine chromicized catgut.

In my first case I used thirty-day catgut to hold the bones in position. I have discarded it in favour of silk on account of the greater tensile strength and durability of the latter.

dislocation unless an operation had been efficiently performed. In my early cases I only operated at a late stage for the relief of pain and prolonged incapacity. I wired the ends together; I invariably found it necessary to remove the wires, because they became loose or caused pain.

The operation I now employ is very simple and very efficient. I now recommend it in every case. Once it has been done the patient can discard all dressings in eight to ten days, and resume work in fourteen days. Two of my patients were playing Rugby football in two months. The procedure is as follows:

1. A curved incision with convexity behind is made from the tip of the acromion to the middle of the posterior border of the clavicle.
2. The flap thus outlined is reflected forward, exposing the acromio-clavicular joints.
3. The inter-articular cartilage is removed, and the ends of the clavicle and acromion process are freshened.
4. Two holes are drilled vertically through the end of the acromion, and also through the outer end of the clavicle.
5. A carefully sterilized strong silk ligature is passed through the clavicle, so that the free ends both project below and the loop is across the top. (Fig. 1.)
6. The free ends are then drawn through the acromion from below upwards. This is best done by the aid of a loop of fine wire. (Figs. 1 and 2.)

## SECTION OF OPHTHALMOLOGY.

WILLIAM GEORGE LAWS, F.R.C.S., President.

### DISCUSSION ON THE SIGNIFICANCE OF RETINAL HAEMORRHAGES.

#### OPENING PAPER

BY

R. FOSTER MOORE, O.B.E., M.A., B.Ch., F.R.C.S.,

Ophthalmic Surgeon, St. Bartholomew's Hospital; Surgeon, Royal London Ophthalmic Hospital.

THE subject which has been chosen for discussion at this meeting is that of retinal haemorrhages, and although it is a subject which has been widely discussed at various meetings and congresses I take it that it is the importance of the subject which has induced the Council to choose it, rather than the expectation that there is anything very fresh to say about it. At any rate, for myself I feel that there is little that I can say which has not previously been under discussion. I have, however, endeavoured to deal with known facts in a different manner.

I suppose we may assume that it is not intended to comprehend all those numerous diseased conditions of the retina with which retinal haemorrhages are associated, such as renal retinitis, retinitis circinata, etc., but rather that we should confine our attention to retinal haemorrhages as such. Cases of trauma or new growths need not be considered.

I should like to state here that it was chiefly the stimulus supplied by reading Dale and Laidlaw's and Dale and Richards's investigations, and Krogh's work on the anatomy and physiology of the capillaries, that induced me to accept our secretary's invitation to take part in this discussion, and I may appropriately here acknowledge my special indebtedness to these investigators.

I propose to deal with the matter under the following sections: I, General considerations. II, The different types of retinal haemorrhages. III, A consideration as to the pathogenesis of the haemorrhages. IV, The changes which retinal haemorrhages undergo.

#### SECTION I.

I put forward the following as a reasonable classification of retinal haemorrhages, excluding such as are due to disease localized in the eye.

##### A. Disorders of Metabolism.

1. Renal disease.
2. Diabetes.
3. Scurvy.

##### B. Diseases of the Haematopoietic System.

1. Arterio-sclerosis.
2. Severe anaemias (or severe cachexia).
3. Leukaemias.
4. Infective endocarditis.
5. Vaquez's disease.
6. Haemophilia.

##### C. Obstruction to the Venous Flow.

1. Thrombosis of the retinal veins.
2. Thrombosis of the cavernous sinus.
3. Subarachnoid haemorrhage.
4. Papilloedema.
5. During birth.
6. Severe compression of the chest.

Let us now consider for a moment the structure of the small vessels as shown by Krogh. The capillaries are, of course, the essential part of the circulatory system; the whole of the rest of this system, whether heart, arteries, or veins, being solely concerned with ensuring that an appropriate supply of blood is delivered to the tissues through the intermediation of the capillaries. Krogh has shown that the capillaries are not tubes which undergo passive dilatation or narrowing, but that actively contractile cells (Rouget cells), which are under nervous control, are incorporated in their walls outside the endothelium, forming a loose meshwork, through the spaces of which free transition between the blood in the capillaries and the fluid in the tissue spaces takes place. By means of these cells the capillaries are capable of extreme constriction or dilatation.

He has shown that in a resting tissue at any one moment a few only of the capillaries are transmitting blood, the remainder being collapsed and empty, but that capillaries which are open at one moment are shortly closed down and neighbouring ones which previously were contracted have now become patent; and this process is repeated again and again, so that all the tissues are adequately supplied. He has shown that in an active tissue all the capillaries transmit blood, and that the number of such capillaries in an active tissue as compared with a resting one may be increased twenty or thirty fold. (Whether it might be possible to find evidence of this phenomenon in the retina by varying the illumination I do not know, but it would certainly be worth trying.) He has shown, too, that in certain circumstances the capillaries may transmit plasma without any contained red cells—a condition to which he applies the term of "plasma-skimming."

So far, then, as the capillaries are concerned we have to deal with vessels composed of one layer of endothelial cells, outside which is a wide-meshed network of contractile cells leaving a large part of the endothelial wall uncovered; so that under nervous control the capillaries may be quite collapsed, they may transmit plasma only, they may be so narrow that a red blood corpuscle is squeezed into a sausage-like shape in passing through, or they may be so greatly dilated that they are several times the diameter of the supplying arteriole. The transition between arterioles with a complete muscular coat and capillaries is sharp and abrupt; on the other hand, the transition between capillaries and venules is more gradual, for the latter have at first, like the capillaries, an outer coat formed of a wide-meshed network of Rouget cells,

through the meshes of which interchange between the blood and tissue fluids can occur as in the capillaries.

In conditions of health there is a very free interchange of fluids, salts, gases, proteins, and even colloids, between the capillaries and the tissue spaces; and this interchange may take place in either direction, for after a large haemorrhage not only is the volume of the blood quickly made good, but the constitution of the plasma is rapidly restored by the transference of the appropriate constituents from the tissues; but in spite of this very complete interchange there is no passage of the cells of the blood into the tissue spaces, and Krogh has shown by the following striking experiment how impervious is the healthy capillary wall to the transmission of minute foreign particles.

Particles of Indian ink are submicroscopic, nevertheless when the capillaries are widely dilated as a result of treatment by histamine, if so much Indian ink is injected into the blood that the plasma, even in the smallest vessels, is made quite grey, even though the plasma passes out very freely through the endothelium into the tissues the minute Indian ink particles are kept back quantitatively within the capillaries. If, then, escape of blood occurs from the capillaries, there must be some special factor or factors which are responsible for its escape.

Ricker and Regendanz performed two experiments on the conjunctiva of rabbits, in one of which the conjunctiva was severely irritated by a mechanical stimulus—namely, finely powdered pumice-stone, which was then washed out. There was immediate strong hyperaemia, and in a few minutes complete stasis, but haemorrhages are not mentioned. In the second experiment a solution of abrine was dropped into the conjunctival sac. There was no immediate effect, but eight hours later there was pronounced hyperaemia, and next day the vessels were much dilated. There was marked capillary stasis and capillary haemorrhages, which increased for several days. Here, then, the haemorrhages seemed to be due to poisoning of the endothelial cells by the abrine; and it is well known that in what one may refer to somewhat roughly as poisoned states of the blood, such as diabetes and renal disease (to mention perhaps the two most prominent), retinal haemorrhages are of frequent occurrence.

Thus it seems evident that there are certain poisons which especially affect capillary walls, so that they no longer maintain an inviolate barrier against the passage of cells from within their lumen; and I suppose it cannot be doubted that toxins may be responsible for retinal haemorrhages, whether it be by means of a gross breach, so to speak, of the capillary wall, or whether by diapedesis between adjoining endothelial cells. I suspect that it is defective nutrition of the endothelium which determines the escape of the blood, and this I suggest is brought about by abnormal constituents in the blood, as in nephritis or diabetes, or perhaps in the anaemias by the defective nature of the blood itself.

There is a structural abnormality in the vessels which may be mentioned. Aneurysms of arteries and veins which are visible to ophthalmoscopic examination have often been described and are well recognized; aneurysmal dilations of the capillaries are figured by Gowers in the second edition of his *Medical Ophthalmoscopy*, and Parrisius states that in individuals who are the subject of vaso-neurotic constitutions—that is, patients in whom frequent changes in the innervation of small vessels occur spontaneously, or from trivial causes, as, for example, those in whom the fingers go quite white or "dead," as they say (due to simultaneous contraction of arteries, capillaries, and veins), sometimes strongly red (dilatation of all vessels), or deep blue (contraction of arterioles with dilatation of capillaries and venules)—that in such individuals at the same moment there may occur, in capillaries lying side by side, some of usual calibre, some enormously dilated, and in some true capillary aneurysms.

#### SECTION II.

##### *Different Types of Retinal Haemorrhages.*

Having considered some of the features concerning the normal capillaries it would seem best, in the next place, to consider haemorrhages as seen with the ophthalmoscope,

to see whether we can gather any guidance from this source as to the pathogenesis of the haemorrhages.

It will not be disputed that retinal haemorrhages are not all of one type, and there are a number which are characteristic in appearance, are easily differentiated, and to some extent are distinctive of different disorders. The following form eight types of haemorrhages which are distinctive in greater or less measure, and from certain of them we can, I believe, obtain some hint as to the mode of escape of blood from the vessels.

1. Flame-shaped haemorrhages.
2. Rosette haemorrhages.
3. Diamond-shaped haemorrhages with pale centres.
4. Gross haemorrhages of mottled appearance.
5. Pre-retinal or subhyaloid haemorrhages.
6. The haemorrhages of infective endocarditis.
7. The haemorrhages associated with subarachnoid haemorrhage.
8. Cotton-wool patches.

Let us consider these in order in a little detail.

1. *Flame-shaped Haemorrhages.*—These no doubt are the commonest type of haemorrhage. They may be exceedingly small, but are seldom very large. They are situated in the nerve fibre layer, and their appearance, like a tongue of flame, is due to their taking on the texture of this layer. They are a common type in renal retinitis, arterio-sclerosis, etc.

2. *Rosette Haemorrhages.*—These are small, are situated in the deeper retinal layers, and are somewhat characteristic of diabetes; they are almost always multiple, more or less circular, and have an irregularly crenate edge.

3. *Diamond-shaped Haemorrhages with a Pale Centre.*—These haemorrhages always remind me a little of the shape of an endothelial cell, the pale centre representing its nucleus. They are seldom large, are certainly seen much more frequently in the anaemias or leukaemias, and are rather distinctive of these conditions; they are quite rare in such conditions as renal disease and arterio-sclerosis. I suspect the pale centre is composed of those elements of the blood (perhaps fibrin and platelets) which last escape from the leak in the vessel before it is finally sealed. In rarer instances the pale centre is replaced by a denser red clot.

4. *Large Mottled Haemorrhages.*—These are gross haemorrhages composed of red areas mottled by white exudate. They usually occur close to the disc and along the temporal vessels, which in parts are completely hidden and in parts emerge for a short distance and disappear again. They occur chiefly in severe vascular disease and are probably due to a leak from a vessel larger than a capillary, although after their complete clearance, when the vessels in the affected area have again become clearly visible, I have sought for, but have failed to discover, any evidence as to the source of the leakage.

5. *Pre-retinal or Subhyaloid Haemorrhages.*—These form a very striking type of haemorrhage, and, as is well known, are most frequent in the macular region. They are of homogeneous texture, they may be multiple, and may show successive layers produced by successive bleedings. When very dense they often have a slaty appearance over their densest parts, and this appearance is also seen in other large haemorrhages of other types. They may occur in vascular disease, and leukaemia is a rather common cause of them. Erythropsia is sometimes complained of.

6. *The Haemorrhages of Infective Endocarditis.*—I suppose there can be no doubt that these are due to the lodgement of minute infected emboli in the retinal vessels, and it seems certain, for anatomical reasons, that they must be situated on the heart side of the capillaries. Few cases of the disease occur in which retinal haemorrhages are not present. It is more common in this disease than in any other to see the blood extending along the vessels as though it were effused into the perivascular sheath.

7. *The Haemorrhages Associated with Subarachnoid Haemorrhage.*—In any case in which there is free blood in the anterior cranial fossa it is free to flow into the loose subarachnoid sheath of the optic nerve. Thus it occurs in fractures involving this region of the skull, in cerebral haemorrhages which have afterwards extended into the subarachnoid space, and in rupture of aneurysms of the circle of Willis. Turnbull has shown that aneurysms of

the circle of Willis occurred in 0.92 per cent. of the autopsies in which the head was examined at the London Hospital, and he and others have made it clear that with few exceptions they are due either to an inborn defect of the middle coats of the arteries or to infective endocarditis, and that syphilis enters very little into their causation. When haemorrhage into the sheath of the nerve takes place haemorrhages in the retina are not infrequently developed. They are large, adjacent to the disc, and usually multiple. It has been suggested that they are brought about by the direct extension of blood from within the sheath of the nerve along the central retinal vessels into the eye, but it is perhaps more probable that the presence of the blood in the sheath obstructs the outflow of the blood from the eye by pressure upon the central retinal vein, where it traverses the subarachnoid space and so is responsible for the haemorrhages. I think one may say that where retinal haemorrhages of this type occur in a patient who has had an apoplectic attack and in whom there are none of the ordinary signs of vascular disease spontaneous subarachnoid haemorrhage should be borne in mind and the cerebro-spinal fluid examined for blood. I have on four occasions diagnosed the condition, but in only one of them was the diagnosis put to the crucial test in the post-mortem room, and in this case it proved to be correct.

8. *Lastly, what I have called Cotton-wool Patches.*—Under this head I should like to make reference to certain patches which occur in the retina which I believe should be properly considered under the heading of haemorrhages—namely, white patches which are seen in the retina in some cases of anaemia. Seen by themselves they are indistinguishable ophthalmoscopically from the cotton-wool patches of renal retinitis. They are usually associated with haemorrhages, but may occur alone. Thus, in 43 cases of secondary anaemia in which retinal haemorrhages were present these white patches were present in 6, and in 2 of these cases no haemorrhages were present. They may be fringed by blood or form a sort of fringe for a haemorrhage, and indeed every gradation between a pure red haemorrhage and a pure white patch may occur. Their especial importance is that when they are associated with haemorrhages, or indeed apart from them, the condition may simulate early renal retinitis so closely as to be indistinguishable from it, and one should remember that severe anaemia is a frequent concomitant of nephritis, and perhaps may be a factor in the production of the ophthalmoscopic changes of this disease. I imagine the patches are produced by infiltration of the retina by fibrin.

### SECTION III.

In the light of the information that we have reviewed in the two previous sections may we now see whether we seem justified in forming any conclusions as to what is the route by which the blood escapes into the tissues and what are the immediate pathological processes which lead to this escape.

Does it occur from arterioles, or capillaries, or venules? does the escape occur by a process of diapedesis or by a gross lesion? is it the result, for instance, of the giving way of small aneurysms, or is there a rupture of a vessel wall? is the escape due to a disease of the vessel wall, or to an altered state of the blood acting on a healthy vessel wall, or are mechanical causes alone sufficient even though the blood and vessels are healthy? It would seem evident that the immediate cause of the escape from the vessels in such divergent conditions as thrombosis of a retinal vein, pernicious anaemia, or a case of infective endocarditis must be very different.

Let us first consider the site of the escape of the blood. May it occur from arterioles? Rupture of the small arteries in the brain is common, is frequently associated with multiple aneurysmal dilatations, and is caused by the giving way of such a dilatation; but what aneurysms have been reported on the retinal arteries have, I think, always been associated with other retinal changes and have probably been of congenital origin; and in the many cases of arterio-sclerosis which I have seen associated with cerebral haemorrhages I do not remember to have seen an aneurysmal dilatation of the retinal arteries.

In the cases of sudden infiltration of the vitreous by blood leading to sudden great loss of sight it is, I think, clear that a vessel of larger calibre than a capillary has given way, but whether this has been on the venous or arterial side I have no direct evidence to offer, although on several occasions I have looked for the source of the bleeding when, the haemorrhages having cleared, the retina has again become to some extent visible. I should think it is indisputable that in infective endocarditis and other cases of septicaemia and pyaemia, where the haemorrhages are brought about by the lodgement of emboli, such haemorrhages occur from arterioles.

We may next give consideration to the capillaries as the source of leakage. We have already seen in Section I that the very essence of capillaries is that they should allow of the freest possible interchange between the blood and the tissue fluids, and at the same time we have seen how impermeable they are to foreign or abnormal constituents so long as their nutrition is maintained.

It seems to me that the picture that is presented to our mind is that of an endothelial cell or cells whose health is impaired by the action of a toxin, to the extent that the endothelial tube is no longer inviolate, but that a defect in it is developed which is sufficiently gross to allow of the escape of the cellular elements of the blood into the tissues; whether such a stoma results from the opening up of the line of junction of separate cells or from a breakdown in the cell itself I should not care to guess. We may remember that red cells are easily distorted, so that they pass through capillaries of much less diameter than themselves, and that they will pass through filter paper which keeps back granules quantitatively much smaller than they are, even though the pressure is no more than the height of the fluid in a funnel, and it may be that this faculty facilitates their escape from within the lumen of the capillary.

I believe, then, that circulating toxins, by acting on the endothelial walls of the capillaries, render their walls permeable to blood cells, and that there are certain toxins which seem to have a specific action in this direction, whereas many others which similarly have a specific action on other tissues have none such on the capillary walls. Thus, to take a single example only, the diphtheric toxin, while potent for heart muscle, does not, except in special cases, lead to haemorrhages in the tissues; on the other hand, the toxins of certain other organisms appear specially to lead to haemorrhages, and perhaps the Koch-Weeks bacillus in the conjunctiva is a fair example of this.

I suggest, then, that the retinal haemorrhages of renal disease and diabetes are probably due to this cause. In the case of the anaemias, leukaemia, and cachexia, I see no reason to suppose that there is necessarily any circulating toxin which causes the haemorrhages, and it seems to me that the likeliest cause is a defect in the nutrition of the endothelium as a result of the depleted quality of the blood or perhaps from defective oxygenation.

#### *Haemorrhages in the Anaemias.*

It may be said in a general way that in any severe anaemia retinal haemorrhages are likely to occur, and especially is this so when the anaemia is the result of a prolonged drain on the body, such as the anaemia which is a part of a severe cachexia from any cause. I doubt whether a patient ever dies of pernicious anaemia or leukaemia without at some time having haemorrhages in the retina. On the other hand, although chlorosis has now become a rare disease I never remember to have seen a retinal haemorrhage in the condition; and I have seen extreme anaemia rapidly produced by loss of blood without haemorrhages occurring in the retina.

We may now inquire whether increased pressure in the capillaries may be responsible for haemorrhages.

It is, of course, well recognized that folk with a high systolic pressure—for example, in renal disease or primary arterio-sclerosis—frequently have retinal haemorrhages, and it is sometimes assumed that it is the increased pressure in the vessels which is directly responsible for the haemorrhages. I believe that the peripheral resistance to

the circulation which is responsible for the increase in the blood pressure is situated in the small arteries, and that the pressure in the capillaries of such patients is not at all raised, but is frequently, and perhaps always, less than the normal—a fact which I believe is demonstrable, as I have pointed out elsewhere.<sup>2</sup> Any drastic reduction in the general blood pressure of such patients, were it in fact possible to bring it about, would only still further reduce the blood supply to the tissues, so that their functions could no longer be efficiently carried out, and the patient's well-being would be still further prejudiced; and indeed I would not be surprised to find that any drastic lowering of the blood pressure of such patients would lead to an increase in retinal haemorrhages.

I do not believe, then, that retinal haemorrhages of arterio-sclerosis are caused by an increase of pressure in the arteries or capillaries; they occur only in cases which are somewhat advanced, and I suggest that the haemorrhage is an expression of the defective circulation through the vessels, so that the nutrition of their endothelium is impaired and consequently a leakage of blood occurs.

If we now turn to the other side of the capillary bed—namely, the veins and venules—Krogh has shown that the small venules are supported by an open meshwork of Rouget cells, and are not completely clothed by a muscle coat, so that they probably act as capillaries for the interchange of substances between the blood and the tissue spaces—a fact which would seem to facilitate leakage from them.

There are a number of conditions where the venous flow from the retina is obstructed in which retinal haemorrhages occur; they form perhaps the most interesting of the cases with which we are concerned, and may be conveniently classified in three groups:

#### *Group A. Cases of general venous engorgement.*

1. General constitutional conditions, such as whooping-cough or vomiting.
2. The haemorrhages produced apparently by the process of birth.
3. Severe compression of the chest.

#### *Group B. Due to a local cause outside the eyeball.*

1. Subarachnoid haemorrhage.
2. Papilloedema.
3. Some cases of thrombosis of the cavernous sinus.

#### *Group C. Due to a cause within the eyeball.*

Obstruction of the central retinal vein or one of its tributaries.

It seems difficult or impossible to avoid the conclusion in all these cases that the back pressure caused by the venous obstruction is the cause of the leakage of blood.

In Group A there is venous engorgement of the whole body, and I think it may be said in a general sort of way that the profusion of the haemorrhages is commensurate with the degree of the engorgement.

In Group B the site of the obstruction in papilloedema and subarachnoid haemorrhages is probably in the central retinal vein where it crosses the subarachnoid sheath of the optic nerve. In thrombosis of the cavernous sinus haemorrhages are inconstant and their incidence may depend upon the anatomical termination of the central retinal vein; if it enters directly into the sinus haemorrhages would be likely to be profuse, but where it ends in the ophthalmic veins the occurrence of haemorrhages may be avoided when the communication between this vein and the angular vein is a free one.

In Group C the obstruction is in the veins of the retina in which thrombosis may occur, or the lumen may be reduced by endophlebitis, or the vein may be pressed upon by a thickened artery.

It is true that in these cases the small vessels may be diseased and add an additional factor, but in the case of birth haemorrhages, the haemorrhages of papilloedema, and those associated with subarachnoid haemorrhages, there is no associated vascular disease, and there can be no doubt that the extreme venous engorgement is transmitted to the venules and capillaries, and so perhaps they are distended to the point of bursting or leakage.

In this connexion I should like to refer to cases, of which I have seen several instances, where there was evidently a hindered outlet of blood from the eye owing to disease of the veins but no complete obstruction, associated with innumerable small retinal haemorrhages in the territory of one tributary or of the whole retinal vein, the

small haemorrhages looking like leaves on a tree, the branches of which were represented by the veins and their smaller tributaries. It seemed impossible to avoid the conclusion that there was some venous obstruction which was of sufficient degree to cause the haemorrhages; and in one case thrombosis of the central vein had occurred in the right eye, and one could not but feel, from the presence of the appearances described above, that it was imminent in the left. Nevertheless the haemorrhages completely disappeared, and ten years later none were present and the eye was still good enough to enable the man to continue his work at a paper-cutting machine, even though it was his only useful eye. Abnormal dilated vessels had formed on the disc, which, it seemed, had provided collateral channels which were sufficient to relieve the obstructed venous outflow.

It would seem, then, that leakage of blood from the arterioles occurs from the lodgement of infected emboli, as in infective endocarditis, from the capillaries, either from poisoning of the endothelium as in renal disease or from impairment of its nutrition as in the anaemias, and from the venules from mechanical causes, as in a hindered venous outlet from the eye.

#### SECTION IV.

##### *On the Changes which take place in Retinal Haemorrhages.*

It is worth while giving some attention to the ophthalmoscopic changes which take place in retinal haemorrhages in the course of their disappearance, and to inquire whether any permanent residue of them remains and whether permanent sight defects occur. It has been shown by a number of observers, and recently by a careful investigation carried out by Juler, that retinal haemorrhages are very common in newborn infants and are apparently produced during the process of birth. Juler found them in 15.5 per cent., and, contrary to what might have been anticipated, he was not able to substantiate that they were most frequent in difficult and prolonged labour. Seeing, then, that 15.5 per cent. of the population have retinal haemorrhages at birth, it is quite evident that in a very small proportion of them, if any, a permanent residue of the haemorrhages persists, or damage to sight is produced.

I have on many occasions carried out observations on all sorts of retinal haemorrhages by making outline drawings, using the retinal vessels as lines of latitude and longitude so to speak, so as to be able to identify exactly the particular haemorrhage which was being watched.

I believe it may be said that all haemorrhages simply fade away, gradually becoming smaller, and undergoing no other change in colour. The length of time required for their complete disappearance varies enormously. Thus, I have seen a small flame-shaped haemorrhage disappear completely in six days, and Mr. Juler tells me that he has seen a haemorrhage in a newborn infant disappear completely in so short a time as four days; this observation has the advantage that the precise time of the development of the haemorrhage is known, whereas in my own observations the time of disappearance has necessarily been taken from the date of discovery of the haemorrhage.

On the other hand, large dense haemorrhages may take many months for their complete absorption. I have notes of large heterogeneous haemorrhages which took more than a year for their complete clearing.<sup>3</sup> In the case of thrombosis of the central retinal vein, where haemorrhages are especially profuse, I have on several occasions seen the retina afterwards become completely free of haemorrhages, though it is much more usual for a few haemorrhages to remain for months or years if they are carefully sought for; it is not, of course, that the same haemorrhages remain for all this period, but fresh ones are developed as the old ones become absorbed. I have seen a case of central vein thrombosis where the haemorrhages cleared completely and eight years afterwards recurred, the fundus having exactly the appearance of a primary thrombosis of the central vein. I have once seen, in a man of 77, what looked like small globules of blood in the retina, which were still present and hardly changed in appearance three years later; and on two occasions I have seen blood in connexion with the

perilental space which I believe had been present for six years. It seems very improbable that blood should remain for so long a period, but without being certain I believe my observation is correct.

We may now inquire as to whether permanent fundus changes may develop as a result of a retinal haemorrhage. I believe it may be stated that haemorrhages, no matter how profuse or large, produce no permanent change in the retina unless the external limiting membrane is lacerated. Unless this occurs no sort of pigmentary change follows, the haemorrhage clears so completely that no residue remains, and the part of the fundus previously involved comes to have a normal appearance, except that where the haemorrhage has been large I have several times seen a few bright dots scattered over the area. Juler's observations supply additional evidence in this direction, for, as already stated, he finds that 15.5 per cent. of the population have haemorrhages in the retina at birth, and it is certain that no such proportion of the general population have abnormal pigmentary fundus changes. I have shown that in cases of thrombosis of the central vein pigmentary changes at the yellow spot are afterwards rather common, but I have little doubt that they are of degenerative origin, and not a residue from the blood, for the changes are limited to the macular area, and I have never seen them in cases of tributary thrombosis; and, further, Williamson-Noble's observations<sup>4</sup> provide definite histological evidence in favour of this view.

With regard to the cotton-wool patches to which I have drawn attention, they, like the haemorrhages, gradually fade away completely and leave no permanent residue; they disappear, however, more rapidly than haemorrhages of similar size, and where they are developed in association with blood, as, for instance, where they form a sort of fringe for a haemorrhage, they disappear long before the haemorrhage has become completely absorbed.

#### GENERAL DISCUSSION.

Dr. C. O. HAWTHORNE (London) emphasized the medical importance of retinal haemorrhages. As such haemorrhages might occur without any recognition by the patient of impaired vision, and as they might be the earliest objective evidence of serious disease, it necessarily followed (1) that every patient should be examined by the ophthalmoscope, and (2) that any patient who was the victim of a retinal haemorrhage should be subjected to a complete clinical examination. No practitioner supervising an acute or prolonged illness was content with a single examination of the heart or the urine, and similarly no practitioner should in like circumstances be content with a single ophthalmoscopic examination. Though no retinal haemorrhages were present on one day it did not follow that they would not be present on the next. An explanation of a retinal haemorrhage in a patient who in other respects was organically sound was not easy. It might be suggested that there were persons with unduly brittle retinal vessels, even as there were persons whose cutaneous vessels yielded to such slight pressure as a friendly grip, with the resulting production of a bruise. Just as certain abnormal qualities of the blood led in different instances to such events as petechiae, ecchymoses, epistaxis, haematemesis, haematuria, etc., it was at least possible that other alterations in blood quality, too subtle perhaps for detection at present, prejudicially affected the integrity of the retinal vessels and thus caused retinal haemorrhages. In any event it was beyond dispute that now and again such haemorrhages occurred apart from appreciable evidence of disease even when the patient's subsequent history was followed over a relatively long course of years. Examples of the clinical value of the recognition of retinal haemorrhage were to be found in glycosuria and nephritis and arterial degeneration; and particularly in difficult cases such as pyrexia without obvious cause, for while in pernicious anaemia and leucocythaemia retinal haemorrhages were the rule, they were not to be expected

in enteric fever, paratyphoid fever, or in tuberculous. Again, joint pains, apt to be labelled "rheumatism," took on a different aspect when the presence of retinal haemorrhages suggested that a septic infection was the true interpretation. In these and other instances retinal haemorrhages had high diagnostic value. The tracing in retinal haemorrhages of specific characters distinguishing between albuminuria and glycosuria might have a certain sporting interest, but could not be commended as a sound diagnostic method. In prognosis retinal haemorrhages played a part subordinate to clinical evidences from other sources. In chronic nephritis, for example, the fact of haemorrhages in the retina influenced the outlook as much or as little as the occurrence or non-occurrence of epistaxis. Both in the one and in the other the event was but a single member in a large series, and it was on the whole of the record, and not on a part of it, that a rational outlook for the future must be based. In all probability it was a sound proposition that a retinal haemorrhage was always preceded by damage, anatomical or nutritional, to the vessel wall.

Mr. G. H. POOLEY (Sheffield) said that in considering the significance of retinal haemorrhages there must be taken into account (1) the character or appearance of the haemorrhage, which varied to a certain extent according to the nature of the morbid process which had caused it, and (2) the age and general condition of the patient. Retinal haemorrhages occurred in the following conditions among others: nephritis, high blood pressure, arterio-sclerosis, diabetes, trauma, thrombosis of retinal veins, glaucoma, and retinal conditions such as retinitis circinata or proliferans. Retinal haemorrhages varied in the depth in which they occurred in the retina. Some were on the surface of the retina—the so-called pre-retinal or subhyaloid haemorrhages. They were D-shaped and occurred in middle age. The blood usually came from the upper temporal vein, and in its descent, owing to the erect posture, covered the macula. The blood was generally reabsorbed within six months, and little, if any, impairment of vision usually, though not invariably, resulted. Some intraretinal haemorrhages were in the retina, but not very deep; these were striate or linear haemorrhages. Others also in the retina were larger, rounded or irregular in shape, and deeper than the striate ones. Many of these intraretinal haemorrhages were due to renal disease. The fewer and the smaller were the intraretinal haemorrhages the better was the prognosis. The absence of oedema of the retina and thickening of the retinal arteries was also very favourable. Conversely, large intraretinal haemorrhages with extensive white patches of oedema and marked thickening of the retinal arteries were signs of a very serious condition, in which the duration of life was calculated in months. This applied to all cases at all ages, though the younger the patient was the more serious was the appearance of retinal haemorrhages due to renal disease. Even if only one or two striate haemorrhages were present and there was no oedema of the retina, the outlook of the patient was grave—far graver than in an older patient. When the renal condition which caused the haemorrhages was secondary to some general infection, such as scarlet fever, the outlook was better, but even then a good many young patients died within three or four years of the appearance of retinal haemorrhages. In young patients, if in addition to rather large retinal haemorrhages there was distinct and considerable oedema of the retina and thickening of the retinal arteries, the prognosis was extremely bad; they seldom lived for twelve months. Often these patients only came to ask for glasses for the relief of headache; they usually had either large or small white kidneys, and died with sad rapidity. The older the patient and the more chronic the lesion of the kidney, the longer would the patient live. Patients over 60 years of age, with striate retinal haemorrhages associated with chronic interstitial nephritis, might live active lives for another decade. Retinal haemorrhages due to unduly high blood pressure were of bad omen, but, though many of these patients did not live more than a couple of years, some might recover and live a long time. One man, aged 65 when seen ten years ago, had then extensive retinal haemorrhages. He was still in good bodily

health, though quite blind. On the whole, in renal disease the significance of retinal haemorrhages was of very serious importance, but, in the case of striate haemorrhages, the patients lived on the whole far longer than had been generally expected. It was only when, in addition to the haemorrhages, there was oedema of the retina and thickening of the arteries, that a very gloomy prognosis should be given. These were the only ones that died within the year; it used to be assumed that all renal cases with retinal haemorrhages did, whereas many of them lived for many years. The significance of the presence of retinal haemorrhages in diabetes was masked by the different response these patients made to treatment. In glaucoma the presence of retinal haemorrhages made the prognosis as bad as it could be. An examination of the retina by an ophthalmic surgeon in consultation with a physician might give valuable information.

Mr. M. L. HINE (London) congratulated Mr. Foster Moore on having so clearly classified the significance of retinal haemorrhages etiologically, but was glad that Mr. Pooley had also considered their significance from the point of view of the patient and their prognosis. He remembered two cases of subhyaloid haemorrhages over the macular area in otherwise healthy young men, both in the cable service. The blood came from retinal vessels below the macula, and both patients regained 6/6 vision. He had to give an opinion as to their return to work in out-of-the-way parts of the world, and advised that neither should be sent out until he had been free from recurrence for two years. In neither case had the haemorrhages returned in two years. He would be glad to know the percentage liability of recurrence in such cases, and the intervals elapsing between recurrences. He corroborated Mr. Foster Moore's statement that some cases of thrombosis of retinal vessels took a long time to clear up, and would not be too gloomy in giving a prognosis in such cases until after a long interval. In one patient he had some years ago at hospital there was thrombosis of the inferior temporal branch of the retinal vein in the right eye with many haemorrhages in the macular area and less than 6/60 vision. After six months the vision had not improved, and he gave a bad prognosis, but nine months later the patient came again to hospital and his vision in that eye was 6/12.

Dr. P. MACDONALD (York) reported another instance of a patient coming for glasses, and extensive retinal haemorrhages being found on examination. The urine was loaded with albumin and a gloomy prognosis was given to the family practitioner. This was many years ago, and the patient was still a vigorous active man; his disabilities, including his albuminuria, seemed to have disappeared.

Dr. A. CHRISTIE REID (Nottingham) thought that the chief significance of Mr. Foster Moore's paper lay in the new conception of haemorrhage which it opened up. The day might be not far distant when they would be able to classify retinal haemorrhages according to the actual blood constituents that had escaped. Haemorrhage without red blood corpuscles might be difficult to distinguish from an exudate, and this again from a transudate. Signs of actual bleeding (red corpuscles) were often sought without success in the undoubtedly haemorrhagic exudates of, say, retinitis circinata. They were still ignorant of the factors determining which of the blood constituents would pass through these very adaptable capillary walls.

Mr. W. H. McMULLEN (London) insisted that to form an accurate estimate of the prognosis in cases of retinal haemorrhages associated with albuminuria examination of the urine alone was not sufficient. A complete testing of the renal functions was necessary.

Mr. H. L. G. LEASK (Glasgow) did not agree with Mr. Pooley that the prognosis was unfavourable in direct proportion to the size of the haemorrhage. A small haemorrhage might be of very serious import and a very large one clear up completely. In a case quoted, of general arterio-sclerosis, with one minute haemorrhage there was a fatal

issue in twelve months. Large haemorrhages in young persons might have a tuberculous basis, and clear up under the appropriate specific treatment.

Mr. E. H. HARRIES-JONES (Northampton) said that in any discussion of prognosis in retinal haemorrhages they must not forget that quite a number of patients developed acute glaucoma.

Dr. E. J. PRIMROSE (Glasgow) mentioned the case of a patient who, at the age of about 38 years, had an extremely profuse infiltration of her right eye, with minute haemorrhages. A few years previously she had had an acute iridocyclitis of the left eye, while the system generally was affected with rheumatism, and there was also a positive Wassermann reaction due to inherited syphilis. These constitutional conditions and the local eye condition were entirely in abeyance, and had been so for some years, when the retinal haemorrhages occurred in the other eye. The Wassermann reaction had been, and continued to be, negative. The retinal haemorrhagic condition was treated without resort to antisyphilitic or antirheumatic remedies, and it completely cleared up, so that from almost blindness she had a vision of 6/6, and ophthalmoscopically no vestige of the retinal haemorrhages could be discovered. Several years had elapsed since then, and though she still had pains in the eye that had had irido-cyclitis, and at these times suffered from rheumatic pains in the joints, the eye that had had the retinal haemorrhages continued to function well and was free from sign or symptom. He did not think albuminuria had been present.

Dr. A. VERREY (Lausanne) always feared retinal haemorrhages, and thought their prognosis was bad in the majority of cases. He insisted on the importance of remembering the possibility of haemorrhagic glaucoma occurring, and referred to the way in which haemorrhagic states of the retina often resulted in increase of tension.

### HIGHER EDUCATION OF GIRLS WITH LITTLE OR NO SIGHT: CHORLEY WOOD COLLEGE.

BY

N. BISHOP HARMAN, M.A., M.B.CANTAB., F.R.C.S. ENG.,  
Senior Ophthalmic Surgeon to the West London Hospital.

Half a dozen years ago the greatest lack in the arrangements in this country for the training of blind children was made good by the establishment of Chorley Wood College by the National Institute for the Blind, and it is fitting that some account should be given of the new venture. There was before that date ample provision for the training of blind children in levels of work corresponding to elementary education; for training in handicrafts in schools and institutions of more advanced type which might be graded with secondary schools; and there were voluntary institutions which specialized in certain arts, such as music. But the provision for higher education was deficient; there was a first-class public school for boys in Worcester College, but there was no corresponding public school for girls. That deficiency was a serious disadvantage to blind girls, particularly of our station of life. The numbers of such girls are happily few, but there are enough to make proper provision for their effective training and education a necessity; the more especially as the blind girl is handicapped in the highest degree; for her the richest field of womanly activity is closed, since motherhood and the care of a home is wellnigh debarred her. It is the more necessary, therefore, that the individual capacities of these girls should receive the highest form of cultivation possible along other lines, so that they may find the joy of life in other forms of service. Before 1921 the only form of blind training available for them was through individual tuition by home teachers of the blind. A very few, despite their handicap, made good in the ordinary roads of education in association with the sighted. But for the most part the education these blind girls of our class received was little more than learning to read and write Braille.

Attention was called to the need of a school for blind girls in the report of the Interdepartmental Committee on the Welfare of the Blind in 1917, but the stress of war

prevented anything being attempted. In January, 1921, the National Institute for the Blind opened a splendid college for girls "with little or no sight" at Chorley Wood in Hertfordshire. I call it a splendid college, and indeed it is. The grounds and buildings will stand comparison in dignity and impressiveness with any modern public school that I know. The mansion which is now the college was built some sixty years ago in the Palladian or domestic classical style. It is a fine specimen of building in good stone and brick, with noble porticoes and windows, great sweeps of lawn, and many quiet pleasaunces, and placed in a position of surprising beauty on the edge of Chorley Wood Common. This common is a high table-land, rugged with gorse and bracken, with a view of tree-crowned heights in the distance beyond the moat-like valleys that protect the common from popular invasion. Judged by our modern English feeling for and reversion to the Tudor cottage style of domestic architecture, noble as this mansion is, it must have been for a private home uncomfortably spacious. A family, even with a generous allowance of guests, must have been lost in it, and perhaps have yearned for some little suite like that of Marie Antoinette buried in the heart of vast Versailles. But as a college it is perfect. Spacious and airy halls, broad shallow-stepped stairs, straight level corridors, a solidity of structure that damps out the noise of internal traffic, and a complete absence of extraneous sounds save the distant calls of birds and cattle. All these features combine to provide that calmness of atmosphere which is true mate to the cultivation of the mind; whilst the spacious rooms, with their admirable lighting, give a brightness that is most attractive to those girls who still possess some little sight. The estate and house was the generous gift of Mr. J. H. Batty; the house has since been remodelled at great cost by the National Institute for the Blind, so that it is now in every way fitted for a college. The interest shown in the college may be gauged by the growing list of benefactors, headed by the King and Queen.

The college receives girls from the age of 7 years and upwards. On occasions a few young adult women have been received into residence for special coaching for university examinations and the like. Pupils have come from all parts of the British Isles, and a few from abroad—for instance, Sweden, Holland, Italy, and South Africa. Terms and holidays conform to the usual public school arrangements. The school work-rooms, dormitories, the food, the care of clothing, and the sanitary arrangements are excellent. On one of my visits there accompanied me a lady of wide experience; she was greatly impressed with the excellence of the domestic side. An ophthalmic surgeon visits the college at the beginning of each term and examines each pupil; the local medical practitioner is the school doctor, and visits regularly; the matron is a trained hospital nurse. Detailed medical records are kept.

The educational staff comprises the headmistress, four full-time, one half-time, and four visiting teachers, all with degrees or their equivalents. The headmistress is Miss Phyllis Monks, M.A., of Girton College, Cambridge, and formerly a mistress of Roedene School and Fulham County Secondary School. So that both by training and experience she is exceptionally qualified to guide pupils who are less standardized than the average public school girl. In an inspection by the Board of Education in 1925 note was made of the generous allowance of staff, but it was added, "it has to be remembered that there are special difficulties in teaching the blind, which are best surmounted when classes are small." The curriculum is of full public school standard, including Scripture, English, geography, history, French, Latin, mathematics, science (of which there is some practical work despite the difficulty thereof), handwork, music (of which much is made), and physical instruction. Braille and typewriting are inevitable; and there are such pleasant tasks as poultry keeping, gardening, domestic crafts, housewifery, raffia and cane work, needlework, spinning, weaving, and the making of pottery. That the level of blind education is able to keep closely to normal standard is due largely to the ever-increasing library of Braille books now available to students. Special boards and type bring all arithmetic

and algebra within reach; spur-wheels, Braille compasses and rulers are used for geometry and trigonometry; relief globes and maps, and many other such devices help to make full mental development on normal lines practicable.

There are thirty-two pupils now in residence; former students number ten. It is early to count successes, but already one has entered Oxford University, another St. Andrews University, and one is now a teacher of English in Sweden; two will shortly start small schools—one in England, another in South Africa.

Recreation has been well thought out. There is "free-time" after dinner, usually occupied by voluntary hand-work, with reading aloud; but impromptu concerts, dances, charades, and debates are popular. A school magazine has been produced, and for so small a company is uncommonly good; the originals are in Braille, but they have been done into typescript for circulation amongst friends. Outdoor games are played on a clear level lawn of half an acre bounded by a wide gravel walk, which makes the guide of safety. A satisfactory ball game has been evolved, something after the fashion of Association football, except that it is played by hand. The ball is of covered wicker-work and in it is a bell which gives by sound the sense of position. So clever have the girls become at this game that on one occasion they beat a team of sighted girls. The girls take a practical share in the work of the house by making their beds, managing meals, caring for the classrooms, and so forth. Thrice a year there is "parents' day," on which the girls entertain their friends and give a concert or other performance. That the girls are thoroughly happy in their college life there can be no manner of doubt. The shy, solitary, self-centred blind girl soon learns through comradeship to cast off that sense of separateness which a physical handicap is apt to engender, and in so doing takes the first step to the acquisition of independence.

The inspection by the Board of Education last year has been referred to. Dr. Eichholz, senior medical officer of the Board, and three of His Majesty's inspectors, Messrs. W. C. Fletcher, T. W. Phillips, and F. Spencer, made a complete examination of the work of the college, and their report has been published in an eight-page pamphlet issued by H.M. Stationery Office. It is a most satisfactory report, and may well be put into the hands of any inquirer.

In conclusion I desire to stress the responsibility of every ophthalmic surgeon, and, indeed, of every medical practitioner, to such of their patients who are blind or nearly blind girls, or, in the terms of the college, "who have little or no sight"; when all has been done for them by way of medical treatment, no greater good can be given them than an introduction to such a college as this. It may be thought that this or that girl may be well taught at home by a succession of capable governesses. But the girl who enters this college will find a happiness beyond compare with the solitary life of the blind girl in the best of homes. To be taught in company with others is infinitely more stimulating to the mind than the monotony of the most assiduous solitary teaching, whilst the play of wits engendered by life in a community such as a public school of itself affords a training that will give the blind girl a capacity for independence of judgement and of action which is an endowment of no mean advantage in these days.

### SLIT-LAMP TECHNIQUE APPLIED TO SIMPLE APPARATUS.

BY

T. HARRISON BUTLER, M.A., M.D. OXON.,

Surgeon, Birmingham Eye Hospital; Honorary Ophthalmic Surgeon, Coventry and Leamington General Hospitals.

THE slit-lamp has greatly amplified that method of examining the eye which is known as oblique illumination. It throws a sharply defined beam of intense light into the eye, a beam which can be narrowed down till it is about one-fortieth of a millimetre in width, and one which can be focused at will upon any point in the anterior half of the eye. The narrow beam gives an "optical section" of the eye; all the structures can be seen in profile, and in consequence accurate localization along the optical axis

of the eye becomes possible. In a word, the slit-lamp gives us the third dimension which was necessary to enable us to visualize the eye as a solid. A second advantage of the slit-lamp is the ability to concentrate a powerful beam upon a reflecting surface and employ this as the source of illumination. Thus the cornea can be examined in light reflected from the iris, and the iris in lens light. There are other variants of illumination which are now so well known that they need not be mentioned.

It is easy to see that the slit-lamp has become indispensable to many ophthalmic surgeons, and that all cases cannot be completely diagnosed without it. Unfortunately, the apparatus is not always available. It is not portable, and not every patient can be brought to it. Some surgeons have more than one consulting-room, and the cost of the instrument forbids its duplication. Fortunately much of the technique that has been developed for the slit-lamp can, to a considerable extent, be carried out with the simple articles that should be found in every consulting-room. A suitable lamp, an electric ophthalmoscope, a condensing lens, and the ordinary or the binocular loupe, intelligently used, will solve many of the problems hitherto reserved for the slit-lamp. The essential feature of the more elaborate apparatus is not the high magnification of the Czapski microscope, but the refined command of the illumination and the localizing power conferred by the slit-lamp. Much of the work accomplished by the instrument can be carried out with the lowest objective, with a magnification of but nine diameters, which is little more than that of the ordinary loupe, and nearly all can be managed with an enlargement of 15. It is therefore obvious that if we can supply a suitable focal beam much can be done with the loupe, if this be used to its best advantage. An effective beam can be gained by two methods: we can focus a bright linear source of light upon the eye with an ordinary condensing lens, or we can use the filament of an electric ophthalmoscope. Both methods are valuable. The latter plan was brought to my notice by Mr. Coulter of Newport.

I have tried out various sources of light. The pencil furnished by a "point o' light" lamp, or by a motor-head-lamp bulb, has not proved so effective as the much simpler half-watt bulb which is found in every house, and which does not need a resistance or transformer to step down the town voltage. A 60-watt lamp, placed at about four feet from the patient, is the best, and can be made to give a streak of bright light. The lower powered bulbs are now badly made, the filament soon hangs in loops, and no longer supplies a linear source of light.

Many electric ophthalmoscopes, especially the Hamblin, will give a parallel beam if the bulb be drawn right back; if they do not they are out of adjustment and should be returned to the maker. This property has been utilized in my pocket slit-lamp made by Messrs. Hamblin. There is no hole in the mirror, and the instrument furnishes a sharp beam of remarkable intensity. The lamp costs £2.

*Half-watt Technique.*—The bulb must be placed at about four feet from the eye of the patient, and at such a height that the plane of the circular filament lies on the line joining the bulb to the eye. If it be higher or lower we get, not a line, but an ellipse of light. The light is focused upon the cornea, and is seen as a bright line. The loupe is held between the thumb and the forefinger by its cover, the middle finger raises the lid, and the ring and little fingers rest upon the patient's forehead. The forehead of the observer rests upon his bent forefinger, and a meticulous focus is obtained by an alteration in the flexion of the ring-finger. We must emphasize the fact that to see such a phenomenon as the actual circulation of the blood with the loupe it is necessary to focus the loupe within a fraction of a millimetre. The condensing lens rests against the surgeon's forehead. By this method the patient and the observer are one, and any movement of the patient does not disturb either the focus of the lens or that of the beam. It is necessary to focus the beam just as accurately as the beam of the slit-lamp, and to learn simultaneously and instinctively to move the combined focus from one object to another. The pocket slit-lamp is used in a similar way.

**Localization.**—The pocket slit-lamp is better for accurate localization than the half-watt lamp. With it we obtain a definite corneal prism, and can determine three zones in the cornea—the epithelial surface, the endothelial surface, and an intermediate zone, the corneal stroma. We can therefore in the cornea say that an object is on the surface, in the substance, or on the back of the cornea. We can do no more, but this rough localization is very valuable. It distinguishes between a deep and a superficial keratitis, and tells us that certain dots are not on the surface of the cornea but are keratic precipitates. This determination is not always easy with an ordinary diffuse oblique illumination. With the half-watt lamp we work from three mirrors: the corneal mirror, the mirror of the anterior capsule, and that of the posterior capsule of the lens. There is no definite corneal prism; the beam is not sharp enough to form one. The pocket slit-lamp shows up the more marked zones of discontinuity in the lens, and affords a fairly accurate localization of opacities. With both the half-watt lamp and the pocket slit-lamp a nuclear cataract is perfectly distinct, and a central opacity can be defined with ease. A lamellar cataract can be localized with the pocket slit-lamp. With both we are able to localize a posterior cortical or capsular cataract, but we cannot differentiate between a cortical and a capsular opacity. The depth of the anterior chamber can be gauged with reasonable accuracy, but we cannot see cells in the aqueous. Increased flare, if marked, is seen with the pocket slit-lamp.

**Methods of Illumination.**—With the exception of retro-illumination from the posterior capsule for the examination of minutiae in the cornea, all the varieties described for the slit-lamp are available. Diffuse illumination is gained by pushing the lens forward within the true focus. That given by the half-watt lamp is far more effective than the dim diffused light furnished by the frosted bulb found in many hospitals, a form of light inefficient for oblique illumination, and inappropriate for retinoscopy. All dark rooms require two lights: a half-watt for focal illumination, and a bright frosted bulb in a Thorington's chimney for retinoscopy. The ordinary light is a bad compromise. Focal illumination is easy to obtain. The beam can be directed at will upon any part of the cornea, or the iris, and can be projected on to any portion of the lens or into the vitreous. Retro-illumination is given from the iris and from the lens as a whole, probably mainly from the posterior capsule. Specular illumination is constantly used. With it under certain conditions we have seen that the endothelial shagreen is visible, but the magnification is insufficient to resolve it into cells. The anterior lens shagreen is a beautiful object, but the posterior is not seen except as a bright area of light. The sutures of the cortex and of the adult nucleus are easily demonstrated. The Y sutures of the embryonic nucleus are observed only under pathological conditions. Scleral scatter is probably of more real value when obtained by simple methods than with the slit-lamp. It is very useful to detect diffuse opacities in the cornea.

**Technique to Find the Lens Shagreen.**—The patient must direct his gaze in such wise that his line of sight bisects the angle between the visual axis of the observer and the illuminating axis; he must look half-way between the lamp and the loupe, and all three lines must lie in the same plane. The surgeon alters his position slightly till he gets the glare of the light from the lens, and he then raises and lowers his head till the shagreen shines out like freshly cast aluminium. A slight alteration in adjustment brings out the sutures of the cortex, which, as we have stated already, are better seen in their entirety with the loupe than with the microscope.

**The Vitreous.**—Much can be gained by the examination of the vitreous with loupe and half-watt lamp. A detached retina is often seen thus which cannot be brought into view with the slit-lamp. Haemorrhages and tumours are detected, and the vitreous fibrils are visible. It is hardly possible to detect a pathological vitreous with the loupe unless very advanced, but asteroid hyalitis at once attracts the attention.

The visible circulation can be seen in a vascularized cornea and at the normal limbus, but the latter is difficult to detect, and is a test of high proficiency with the loupe.

It probably calls for exceptional eyesight and for dark adaptation. The visible circulation in a pannus can occasionally be seen in daylight with the light of a half-watt lamp and loupe. Very occasionally focal illumination of the retina by the filament of the ophthalmoscope will demonstrate the circulation in the smaller retinal vessels. This phenomenon has been observed, not only by the author, but by Mr. Rudd, surgical registrar to the Birmingham Eye Hospital, and quite independently.

**Technique to See the Visible Circulation.**—In all cases even in the retina, the vessel must be viewed by retro-illumination. In the case of the limbus the light is focused on to the sclera in such wise that it is reflected back through a conjunctival vessel to the eye of the observer. Corneal vessels are illuminated from the iris, and retinal vessels from a deeper layer of the retina.

The pocket slit-lamp is of very real value to one trained in slit-lamp technique who not only knows exactly how to manipulate the light, but also realizes what he is looking for. An object previously invisible with the loupe is often seen perfectly when it has been examined with the slit-lamp.

## NAGEL'S ANOMALOSCOPE

BY

ARNOLD VERREY, M.D.,

Lausanne.

(Abstract.)

**Model I** of Nagel's anomaloscope enables an investigator to look for Rayleigh's equation (lithium red mixed with thallium green, equal to sodium yellow). It is by means of this match that anomalous trichromies are best detected. Not only is the knowledge gained, as by other ways, such as lanterns and isochromatic tables, that these patients are deficient in colour perception, but an exact diagnosis of their defect can be made. With this apparatus any source of light can be used, but Rayleigh's equation will not be the same for the different kinds of light. Three slits let in rays which divide into their components on three prisms disposed in the centre of the apparatus. The first two are twin slits, and use is made of the green rays of the one and the red rays of the other. The combined breadth of these two slits moving together is equal to one millimetre, so that it is possible to get pure green, pure red, or a mixture of both. That mixture is matched with yellow, of different luminosities, let in by the third slit, which is independent of the twin slits.

If electric light is used, normal people have an exact match between the mixture and yellow when the red slit is open to three-quarters of its breadth and the green slit to one-quarter only; the yellow must be of low luminosity, the slit being open to one-quarter only. That equation is an "exact match," the sensitiveness for colours of normal people enabling them to note the least change produced in the mixture if the proportion of red and green is changed. Abnormal people can give all kinds of abnormal matches—from those who find such matches, with more green and less red than normal people, or vice versa, and those who find "match regions" in which many matches are possible; the latter show in that way diminution of sensitiveness for both colours at the same time.

While Model I permits researches for green and red only, Model II, with its special device, is a real spectroscopic, allowing all kinds of different matches to be made, including a blue equation, which renders possible the discovery of diminution of sensitiveness for blue. It can also be used as a simple spectroscopic; by means of the spectrum a diagnosis is very much facilitated. Detection is rapid of shortening in the red or the blue end, and of neutral sections in the yellow, green, or blue-green parts of the spectrum, as they may be found in tritanopes (blue blind), deuteranopes (green blind), or protanopes (red blind).

Diminution of blue perception seems a very rare condition as a congenital dyschromatopsy, but is much more frequent in acquired dyschromatopsy. Macular blue blindness seems to be found not only in affections of the retina, but in disorders of the optic nerve alone. In these last affections sensitiveness for blue is often more diminished than for red and green.

The author is persuaded that if macular sensitiveness for blue was tested otherwise than with the perimeter only, means of classifying cases of atrophy of the optic nerve in an earlier stage of the affection would certainly be found. For all these purposes Nagel's anomaloscope is a most handy and practical apparatus.

### STEAMY CORNEA IN CASES OF NON-INFLAMMATORY INCREASED TENSION.

BY

GEORGE YOUNG, M.D.,

Ophthalmic Surgeon, Essex County Hospital, Colchester.

(Abstract.)

No satisfactory explanation of steamy cornea has yet been proposed. It cannot be due to an exudate, because the cornea is non-vascular, nor can it be attributed to the forcing in of aqueous humour, since Descemet's membrane is impermeable. It is seen in pressing on enucleated eyes, and disappears immediately the pressure is relaxed. Personal experiments show that pressure on the eye will first produce rapid restriction of the visual field, then of vision, the fixation point disappearing last. The subject of my next investigation may be the estimation by means of a suitably constructed dynamometer of the pressure in grams required to obliterate vision in a large number of normal eyes. Any findings below the minimum probably indicate the presence of high tension. With very light pressure, sufficient only to constrict the peripheral field, the test types at 6 metres show duplication of the letters, and lines of print at reading distance show shadowy images, which change their relative position as the pressure is altered. The image of the Javal mires are clean cut in normal corneae, even when the fixation is changed from the centre of the tube to one edge or the other. In steamy cornea with quite smooth epithelium the images show duplication of the edges of the mires varying with the change of fixation. I suggest that possibly there is a shifting of the surface epithelium causing polarization of light, and perhaps a shifting of the corneal layers, causing the iris pattern to look smudged where there is certainly no inflammatory reason for this appearance. This also causes us to see objects duplicated when we press our corneae. The duplication of the Javal image might well be due to a second, feebler image being reflected from the second layer of epithelium, these layers being extremely thin. Less weighty, perhaps, though suggestive, is evidence derived from the examination of microscopical sections. Corneal epithelium is found to be laid down very regularly, like bricks, in the normal cornea, the cells being all tumbled about in old-standing glaucoma. A shredding of the corneal layers is found to be quite regular and symmetrical in normal sections, while in glaucoma cases it often appears that in separating under the microtome they have shifted against each other, the meshes thus formed appearing distorted and giving an appearance of traction that has been relaxed. Slit-lamp experts might be able to clear up this point, for in the Javal image of steamy cornea, if a miotic is instilled and it be viewed after the steaminess has vanished, the image no longer appears duplicated. I suggest that if certain fixed points on the surface of the cornea were observed—for instance, in their relative position to a certain patch of endothelium, before and after the administration of a miotic—some knowledge might be gained.

#### DISCUSSION.

Mr. BASIL GRAVES (London) suggested that, when speaking of a "dull cornea," they must distinguish between a simple dulling of the view of the iris pattern—a sign used in the clinical examination of glaucoma cases—as the result of an abnormality of the cornea through which the iris was viewed, and a dulling of the corneal reflex which produced, for example, the window image—a manifestation dependent on a smooth surface of the epithelium; in fact, the thin capillary layer of tear fluid on the epithelial surface was the actual mirror. He had always understood that the essential alteration of the corneal epithelium when the tension was raised was due to microscopic globules of fluid collecting at first between the

larger basal cells of the epithelium on the face of Bowman's membrane. Such fluid vacuoles were often seen by slit-lamp technique in cases in which the tension was not raised; in certain cases of iridocyclitis they were familiar to slit-lamp students. When present thus, in fine degree, they did not give rise to any disturbance of the surface contour of the epithelium, and hence the mirror effect of the surface of the epithelium was not impaired—the window reflex was still bright. But if these droplets became more numerous they coalesced, and gave rise within the epithelium to droplets of such size that they impaired the surface contour of the epithelium, and hence impaired the mirror properties of its surface. At the same time it was conceivable that the transmitting qualities of the epithelium so affected were sufficiently poor that the view through it of deeper structures, such as the iris pattern, was poor. In connexion with this droplet formation it might be pointed out that Vogt early drew attention to the normal haze, by retro-illumination, of that part of the epithelium which was near its vascular supply—namely, the corneal epithelium near the limbus; this was physiological. Whatever caused this, be it a physiological "oedema," the internal condition of the epithelium was insufficient to disturb its surface contour, and hence the mirror properties of the moist surface of the epithelium here were, in the normal, quite good. These explanations were put forward without intending to furnish a destructive criticism of Dr. George Young's hypothesis. There might be doubling of images when the cornea was pressed on in Dr. Young's experiment; it might be explained simply by the astigmatism caused by pressure on the globe. Mr. Graves had had no previous opportunity of considering Dr. Young's views, which he then heard for the first time. Apparatus made by Messrs. Zeiss was readily available for examination of the eye by polarized light, a polarimeter being available for the arc slit-lamp and an analyser for Koeppe's special microscope made for use with the slit-lamp attachment.

In reply to Mr. Bishop Harman, Dr. GEORGE YOUNG said that he thought the disappearance of the steaminess after corneal section was rather in favour of his view than against it, because the dislocation of the corneal layers was likewise released, and it mattered little whether they were relaxed by the miotic or by corneal section.

### SECTION OF ANAESTHETICS.

SAMUEL JOHNSTON, M.D., President.

#### DISCUSSION ON

#### NEWER GAS ANAESTHETICS: SOME COMPARATIVE CONSIDERATIONS.

#### OPENING PAPERS.

I.—F. H. McMECHAN, M.A., M.D.,

Secretary-General, Associated Anaesthetists of the United States and Canada; Editor, Executive Secretary, International Anaesthesia Research Society.

It has been said that the ideal anaesthetic gas should be one (a) with a sufficient solubility in water (plasma) to be carried to the central nervous system, and (b) such a high degree of solubility in the lipoids as to lead to its differential accumulation there. Further, such an ideal anaesthetic (c) should leave the body promptly and entirely unchanged (V. E. Henderson).

#### Contrasting Viewpoints.

Although some of the so-called newer gas anaesthetics have been investigated experimentally and tried out clinically in the past, nitrous oxide is the only anaesthetic gas that has held its place with such anaesthetics as ether and chloroform since the very beginnings of actual painless surgery. In so doing it has lived up to the expectations of Horace Wells, who in his day steadfastly maintained its superiority, not only in dentistry, but in surgery as well. Of course, Andrews of Chicago gave nitrous oxide a new lease of life in establishing its use with oxygen and introducing the non-asphyxial era of gas-oxygen anaesthesia.

## NEWER GAS ANAESTHETICS.

Since then, despite its narrow margin of anaesthesia, its besetting problem of anoxaemia, and the skill and equipment required for its satisfactory use, to those who have mastered both the physics and physiology of its administration nitrous oxide-oxygen remains the unrivalled method of anaesthesia for any and all operative procedures in normal or the "worst risk" patients. Those who maintain this attitude have not found that a comparative balancing of advantages and disadvantages warrants the replacement of nitrous oxide with either acetylene, ethylene, or propylene. Their greatest concession is the use of one or the other of these newer gas anaesthetics as a synergist in combination with nitrous oxide-oxygen. Those who, for various reasons, have not elected to pursue nitrous oxide-oxygen anaesthesia to its ultimate possibilities have found in the newer gas anaesthetics a somewhat less exacting technique, a broader margin of anaesthesia, as well as an extended scope and utility in the domain of surgical procedures without appreciably any more harm to the patients. Dissension among anaesthetists or a scientific feud based on this difference in attitude would be deplorable; especially as interest in the widespread use of the newer gas anaesthetics promises an era of physiological anaesthesia and research that nitrous oxide-oxygen has never been able to promote or secure alone. Curiously enough, in a certain sense, this newer era of gas-oxygen anaesthesia harks back to the first conceptions of surgical anaesthesia in an older era of "pneumatics" in which some of the gases now in use were first discovered and used.

*Nitrogen and Hydrogen Anaesthesia.*

In this connexion it should not be overlooked that many of Nature's elements are potentially anaesthetics, and are only inefficiently so because the human body cannot use them in certain chemical forms for entirely satisfactory anaesthetic effect.

Thus nitrous oxide may be considered as the practical form of nitrogen anaesthesia. Since unconsciousness may be produced with difficulty by administering nitrogen with less oxygen than is contained in air, there must be some difference between it and nitrous oxide-oxygen which produces anaesthesia with such ease. This difference seems to be in the comparative solubility of the two gases. Nitrogen is nearly insoluble in the body fluids and leaves oxygen free access; while nitrous oxide is more than one hundred times as soluble in the blood serum as oxygen. Hence, although nitrous oxide of itself has no known action upon the cells and tissues of the body and is only acted upon by other chemical substances with the greatest difficulty, it reaches the tissues more readily and thus restricts the volume of oxygen available for metabolism and induces the anaesthetic effect.

A curious side issue of nitrous oxide-oxygen anaesthesia is this: Its margin of anaesthesia is so narrow that to be entirely successful and satisfactory almost the last vestige of nitrogen must be displaced in the body by nitrous oxide, and this is exactly what is attempted in the clinical technique of "secondary saturation."

From this same viewpoint hydrogen anaesthesia has been the predominant basic method during the past eighty-odd years of actual surgical narcosis. Hydrogen-oxygen is a somewhat more effective anaesthetic than a nitrogen-oxygen mixture, but equally difficult to handle. It is not at all surprising, however, that some of the unsaturated hydrocarbons, now challenging attention as the newer gas anaesthetics, should be proving themselves effective, since they are in reality merely gaseous counterparts of the commoner liquid anaesthetics (ether, chloroform, and ethyl chloride) that have withstood the tests of time and routine use.

Now, as during the past, these same two elements, nitrogen and hydrogen, compete for superiority in anaesthesia, but on a more even footing. While certain physico-chemical differentials still persist to the advantage or disadvantage of each, both elements are now being used in their most effective forms by means of perfected gas methods and apparatus as well as impartially with oxygen.

*Theories of Anaesthesia.*

A consideration of certain developments in the theory of anaesthesia will help to a better understanding of these

physico-chemical differentials. Recently an explanation of the phenomenon of anaesthesia has been attempted in relation to the newer physics of the atom. By placing two guinea-pigs in circuit with each other and a very sensitive galvanometer, it was found that, irrespective of different initial potentials, the anaesthetized animal always became more and more electro-positive to the other as anaesthesia deepened, and less positive as anaesthesia disappeared. This may seem rather inexplicable until it is recalled that the only actual electricity is negative. From this it may be assumed that one of the basic reactions of anaesthesia (if not its fundamental mechanism) is a decreasing electro-negative potential.

It is a further noteworthy fact that oxygen is the pre-dominating negative element in nature, and as such, oxidation may be looked upon, in relation to the phenomenon of anaesthesia, as identical with electro-negative potential. Anaesthesia on this basis would involve a decreasing metabolism.

Further investigations on single guinea-pigs under various gas anaesthetics disclosed an interesting differential between nitrogen and hydrogen reactions. The hydrocarbon anaesthetics (ether, chloroform, and hydrogen-oxygen) gave very definite increases in voltage, while nitrous oxide and carbon dioxide almost as proportionately decreased voltage for similar depths of anaesthesia (E. A. Tyler and D. C. A. Butts).

So much for a concept of the phenomenon of anaesthesia that may further intrigue the research physicist and biochemist, and may interpret anaesthetic reaction in subtler terms of protons and electrons as well as the colloidal chemistry of cellular constituents.

Another concept of anaesthesia, the metabolic, offers more practical possibilities to the clinical anaesthetist. This concept has been detailed as a workaday basis of gas-oxygen methods of anaesthesia. Life depends upon oxidation much as a fire in a stove depends upon oxygen. Let the flame represent consciousness (and sensation to pain). Since metabolism, or combustion measured by the oxygen consumption, is reduced in normal sleep and in anaesthesia under various drugs, and since a restriction in the oxygen administered also produces unconsciousness, it appears that anaesthesia is the result of suboxia of the nervous system.

Like the fire in a stove, unconsciousness, it appears that the flame—may be extinguished without "soaking" fire in at least two ways: First, indirectly by "soaking" the fuel, which physically or chemically hinders combustion even with an open draught. This seems to apply to such anaesthetics as ether and chloroform, since they attack the lipoids contained in all cells, and in addition to producing unconsciousness and loss of pain, also disorganize the specialized functions of the kidney, liver, and other organs containing relatively large amounts of lipoids acted upon by these drugs. The heart is less affected because it contains less lipid, but it also suffers considerably through its connexion with the nervous system, which is rich in these substances. Ether and chloroform are not only powerful anaesthetics, but on account of their high boiling point linger in the system and are only slowly eliminated, giving time for undesirable chemical by-effects. In this connexion the newer gas anaesthetics are more desirable than their liquid counterparts because their extremely low boiling points offset their lipid solubility and the rapidity of their elimination obviates serious biochemical complications.

A second method for the reduction of the fire in a stove consists in the ordinary direct regulation of the draught, or the mechanical restriction of oxygen. This is analogous to the control of anaesthesia by the regulation of the oxygen percentage in gas-oxygen mixtures. This is more essentially the way in which nitrous oxide (and carbon dioxide) produces the anaesthetic effect. With practically no action upon the cells, tissues, and organs of the body, nitrous oxide, on account of its solubility in plasma, restricts the volume of oxygen available for metabolism. Anaesthesia then results from reduction of combustion in the nervous system.

In this connexion it must also be realized that the human body is a stove containing many fuels of varying combustibility, and that certain vital functions are carried on

at entirely different levels and intensities of metabolism. Thus nervous tissue requires almost twice as much oxygen as other tissues and also contains comparatively excessive amounts of lipoids; therefore, its special functions may be suspended (1) by the effect of oxygen restriction; and (2) partial saturation with lipid-soluble anaesthetics, long before other vital functions are infringed upon (E. L. McKesson).

#### *The Acid-Base Equilibrium.*

These factors of oxygen restriction and lipid saturation in relation to gas-oxygen anaesthesia involve changes in the acid-base equilibrium, or hydrogen-ion concentration and  $\text{CO}_2$  combining power, which is a further basic consideration in the conservation of the alkaline reserve. These changes, depending on their extent, may both influence the sort of anaesthesia secured and the types of complications presenting.

In making these changes in acid-base equilibrium as negligible as possible certain details of preparation and technical points in administration are essential:

1. Such premedication as will (a) stabilize the circulation; (b) bring the basal metabolic rate as near to normal as possible; and (c) re-establish and maintain the alkaline reserve, should be used to full effect.

2. The oxygen percentage in the gas mixture should approach the permissible maximum that obviates anoxaemia without invalidating the plane of anaesthesia required for the surgical procedure.

3. Rebreathing (preferably fractional) should be utilized to provide carbon dioxide control for any desirable manipulation of respiratory function, especially in avoiding over-ventilation and consequent acapnia.

When these essentials are observed all sorts of gas-oxygen anaesthetics (nitrous oxide, acetylene, ethylene, propylene) may be more easily given, are more efficient, and any possible by-effects are reduced to a negligible minimum.

If the various gas-oxygen anaesthetics have any claim to superiority more important than any other, it is that, even under prolonged administration, the blood pressures are not inclined to fall. To clinch this, however, it is also vitally necessary to use (digitalization) as will conserve myocardial efficiency, and such transfusions (blood, salines) as will maintain not only a volume flow sufficient for vital functions, but also a blood stream capable of carrying on oxygenation.

Increased metabolism makes any method of gas-oxygen anaesthesia more difficult because the intensified oxygen need narrows the range of anaesthesia. Plus basal metabolic rates should be brought nearer normal by means of proper sedatives (morphine, hyoscine, quinine, chloral, Lugol's solution, and certain endocrines—ovary, pancreas, liver extract), not only for the safety of the patient, but also for the convenience of the surgeon and anaesthetist in securing more satisfactory anaesthesia.

On the contrary, in the presence of minus basal metabolic rates patients may be unusually susceptible to gas-oxygen anaesthesia, and danger may be involved in the further depression of metabolism by the anaesthetic. Under such conditions efforts should be made to raise the basal metabolic rate more nearly to normal by stimulative therapy (atropine, caffeine, and certain endocrines—adrenaline, pituitrin, thyroid).

The problems of anoxic acidosis and acapnic alkalosis are definitely bound up with conservation of the alkaline reserve in relation to the patient's blood and tissue chemistry reactions, as well as to the technique of administration. If the alkaline reserve can be established at the approximate normal by means of carbohydrates, fruit juices, and alkalis, and the toxæmias of disease and pathology can be counteracted by insulin-glucose, then gas-oxygen anaesthesia scarcely affect either the carbon dioxide combining power or the hydrogen-ion concentration unless the technique of administration involves a tendency to acidosis from the anoxaemia of oxygen want, or alkalosis from the acapnia of over-ventilation and carbon dioxide depletion.

#### *By-Effects of Impure Gases.*

With the fundamental concepts of the phenomena of narcosis already as the other essentials underlying all anaesthesia, duly in mind, the various anaesthetics, available for routine use may be compared for comparative aspects and relations.

Surprising as it may seem, even the anaesthetics that have been longest in use are not yet supplied in absolute and constant purity. Witness the efforts to make a purer ether by means of crystallization with benzidine; to prevent deterioration by production and packing in the presence of inert gases; or to enhance potency by the incorporation of synergists. Even now a new chapter in the current literature of anaesthesia is being written on the by-effects of ether deterioration impurities, and promises some rather startling revelations.

Nitrous oxide still provides its quota of occasional drawbacks and impurities—too much moisture, nitrogen dilution, definite nitric oxide and ammonia contamination, as well as variegated organic odours. Witness, again, the effort to dry intensively, eliminate divided metals, and deodorize with activated carbon.

With the newer gas anaesthetics both purification during manufacture and prevention of deterioration during storage are still besetting difficulties. There may be hydrogen or carbon dioxide dilution, as well as aldehyde and peroxide, sulphur, and phosphine, or, worst of all, carbon monoxide contamination. Even oxygen for use with anaesthetics may be diluted with nitrogen or hydrogen, and carbon dioxide for resuscitation may contain carbon monoxide.

The more intensively gas anaesthetics are dried the better they lend themselves to use without inconvenient freezing of valves and connexions, and serious interruptions of flow and volume. It is understood that nitrous oxide can now be dried to a moisture content of 0.005 per cent. The acetone and ether coefficients of acetylene and ethylene seem to provide the same practical advantage while also acting as solvents and allowing an equal gallonage of gas to be compressed in a given cylinder under much lower than the usual pressures.

Seemingly low and inconsequential dilutions of anaesthetic gases or oxygen with hydrogen or nitrogen in the cylinder may so narrow the range of percentage mixtures that anaesthesia may become very difficult or entirely unsatisfactory and the indicated oxygen percentages quite deceptive.

Certain impurities in anaesthetics may merely involve disagreeable odours or tastes (sulphur, phosphine); others may be responsible for nausea and vomiting (aldehydes, peroxides); while still others may induce pathological conditions leading to endangering complications or even death (nitric oxide, ethylene oxide, carbon monoxide). As most of these are effective when present in traces represented by percentages in the second to fourth decimal places, their absolute elimination is imperative.

#### *Comparative Potency and Toxicity.*

There is some confusion about the comparative potency and toxicity of the various gas anaesthetics, partly because most of them, like nitrous oxide, are eliminated intact, and are therefore looked upon as being equally "inert"; and also on account of the fact that some admit of complete and satisfactory anaesthesia in the presence of percentages of oxygen higher than are contained in air, and even further dilutions of the percentage gas mixture with the more insoluble gases.

However, in studying potency and toxicity in relation to minimal and maximal anaesthetic and lethal dosage, the series of gas anaesthetics may be considered as having somewhat the following gradients, with ethylene as unity: nitrous oxide 0.85; ethylene 1; acetylene 1.5; propylene 2.25; butylene 4.5; and amylene 15.

A further clinical concept of these gradients may be had by a comparison of the usual percentage mixtures of these gases and oxygen for the induction and maintenance of anaesthesia. In a schematic way it may be said that each

higher member of the series of gases kills readily at the same percentage mixtures at which the previous one maintains safe anaesthesia.

Normally nitrous oxide has the narrowest margin of anaesthesia and the most limited range of percentage mixtures. Not infrequently in pure gas-oxygen administration a leeway of 1 per cent. in the oxygen percentage may definitely determine the control of anaesthesia. Induction may be accomplished either with 100 per cent. nitrous oxide followed by oxygen or by 93 per cent. nitrous oxide and 7 per cent. oxygen; or a combination of both methods. During maintenance 10 to 15 per cent. oxygen is rarely exceeded, except in the presence of shock, haemorrhage, anaemias, profound sepsis, toxæmia, or cachexia.

Under such conditions the required oxygen percentage may mount to 35, 50, 60, or even higher. Surgical relaxation may be secured by the technique of "secondary saturation" or by the use of synergists. At this point it should be noted that the usual slight dusiness of colour under nitrous oxide-oxygen anaesthesia is no more an indication of cyanosis than the peculiar rosy blush under ethylene-oxygen is an assurance that no anoxaemia is present.

With ethylene it is usually possible to induce anaesthesia with mixtures of 90 to 85 per cent. ethylene and 10 to 15 per cent. oxygen from the beginning. During maintenance the required oxygen percentage may rise to 20 per cent. or more; and better surgical relaxation frequently follows short periods of oxygen up to 40 and 50 per cent. mixtures. Ethylene is thus shown to be slightly cumulative during its administration; although, on account of its low boiling point ( $-137^{\circ}$  F.), it is almost as rapidly eliminated as nitrous oxide. This slightly cumulative effect, being due to a higher solubility and some sort of undisclosed and transient physical combination with the lipoids, determines the higher oxygen need, a somewhat wider margin of anaesthesia, and a more intensive obtundent or analgesic effect.

The popularity and widespread use of ethylene has been made possible because ethylene and nitrous oxide are so nearly alike in physical properties that apparatus calibrated for nitrous oxide can be used for ethylene with a margin of error that merely gives a slightly misleading idea of higher oxygen percentages than really obtain. Under similar conditions of administration the increased oxygen range with ethylene does not differ much more than from 3 to 7 per cent. in comparison with nitrous oxide. As with nitrous oxide, the pathological conditions already mentioned demand excessive oxygen percentages. The use of synergists with ethylene for surgical relaxation, especially in abdominal operations, is still rather routine. Very curiously some patients who are resistant to nitrous oxide are more susceptible to ethylene and vice versa. Ethylene may readily be used in sequence or combination with nitrous oxide through the same apparatus with proper attachments; many anaesthetists prefer nitrous oxide for the induction and recovery phases of ethylene anaesthesia (A. D. Luckhardt, W. Easson Brown, T. C. Herb).

Acetylene, according to its place in the series of hydrocarbon gases, should be a weaker anaesthetic than ethylene. The fact that it is compressed with acetone, and that acetone has narcotic properties, may account for its apparently increased clinical potency. Ethylene made with an ether coefficient shows this same increased potency.

Acetylene anaesthesia may be induced in the presence of 20 per cent. oxygen, which may be increased to 30 per cent. in a minute or two. During maintenance the greater solubility and cumulative effect of acetylene usually require an increase of 5 per cent. oxygen and a similar decrease of acetylene in the anaesthetic mixture every five minutes. Thus the closing steps of a long operation may be done under 30 to 40 per cent. acetylene and 70 to 60 per cent. oxygen. Apparatus for acetylene anaesthesia should be especially calibrated for that gas, and the acetone vapour may be eliminated by means of a small filter of activated carbon.

The rapidity with which the oxygen percentage has to be increased during acetylene anaesthesia will depend in great measure on the pathological condition of the patient and the necessity for surgical relaxation. It is being found

that, in spite of the apparently greater potency and toxicity of acetylene, it is still sufficiently innocuous that re-breathing during its administration is quite as feasible as with nitrous oxide (H. Wieland, A. and J. D. Goldman).

Propylene is the only other of the newer gas anaesthetics that has been tried out in the operating-room. Experimentally it offered some unique possibilities: (a) it was more potent than ethylene or acetylene without being too toxic; (b) it could be used satisfactorily with percentages of oxygen that obviated anoxaemia and maintained the alkaline reserve; and (c) more than this, a third gas (nitrogen) could be used at the same time to render the anaesthetic mixture non-explosive to static and perhaps to other sources of ignition as well.

While differing somewhat in relation to the sort of experimental animals used, in a general way propylene concentrations of from 35 to 50 per cent. are effective for induction, and 20 to 40 per cent. for continuing anaesthesia. Usually percentage ranges of from 25 to 35 per cent. suffice for meeting the oxygen need, and the remainder of the mixture may be a third gas (nitrogen). At 60 per cent. concentration propylene causes a slow and at 70 per cent. a rapid fall in blood pressure; while concentrations of from 75 to 80 per cent. are rapidly lethal.

Experimentally low concentrations of propylene have a wide margin of safety—thus in white rats anaesthesia may be induced by 70 per cent. propylene within three minutes, and respiratory failure occurs after eighteen to twenty minutes; but while 55 per cent. propylene will also induce anaesthesia in three to six minutes, this concentration may be continued for seven hours before respiratory failure sets in.

Propylene has been used in a brief series (nine) of operations in the three-gases mixture already mentioned (propylene-oxygen-nitrogen), and while induction, anaesthesia, relaxation, and immediate recovery were satisfactory, profound circulatory collapse occurred in all but two of the patients five to seven hours after operation. Fortunately remedial measures were effective and all the patients recovered.

Beginning with propylene, the newer gas anaesthetics of the hydrocarbon series show by-effects that, for the present, challenge their safety and utility in clinical anaesthesia. It must be frankly admitted that the clinical trial of propylene was in no sense final—the apparatus was not calibrated for propylene and was a makeshift for the use of three gases; and further than that, an accurate technique for three-gases anaesthesia has not yet been developed and its physiology is still unrevealed. These considerations are an alluring prospect to the anaesthetist, and offer a new world of conquest. In so far as propylene itself is concerned with remote circulatory collapse, it was found by electro-cardiographic studies that even in non-anaesthetic concentrations it causes ectopic heart beats. Propylene is not entirely free from a tendency to rigidity of a peculiar type that is more pronounced with butylene.

Induction with butylene with just anaesthetic percentages is relatively prolonged and complicated by a clonic type of rigidity of the extremities such as is seen in decerebrate animals under light ether or as so-called "ether tremor" in clinical anaesthesia. This clonus may continue during complete anaesthesia. While 30 per cent. butylene will maintain anaesthesia (in cats), even with this percentage blood pressure is lower than normal, and under 40 per cent. butylene the blood pressure is very low. The same disadvantages pertain to amylene.

Experiments with methane, propane, pentane, and heptane do not offer any hope of a satisfactory clinical anaesthetic. Their anaesthetic action is variable and uncertain; their toxic and anaesthetic doses are too close together; their effects on respiration and circulation are variable and undesirable; and secondary stimulation may persist when anaesthesia appears to be complete (V. E. Henderson, W. Easson Brown, Lloyd K. Riggs, J. T. Halsey, Ansel Caine).

The several newer gas anaesthetics that have secured a place in clinical anaesthesia seem to have distinctive entities, but their differences are more apparent than real. Conceivably anaesthesia occurs when a certain, still unknown, concentration is secured in the nerve cell, which,

when expressed in volumes per cent., is the same for all anaesthetic gases. This concept is quite applicable to the newer gas anaesthetics under discussion, because their differential variables in (1) concentration in the inspired air, blood, and tissues; (2) solubility in plasma and lipoids; (3) rates of diffusion; and (4) partial pressures during administration, all tend towards establishing a unity of effect in a proportional ratio of the determining factors involved.

#### *Saturation and Elimination.*

In rapidity of saturation for anaesthesia and elimination for recovery, the newer gas anaesthetics conform to the same physico-chemical characteristics and sequence of gradients that determine their potency and toxicity. While nitrous oxide and ethylene, as would be expected, achieve their saturation and elimination more quickly than acetylene, even its rapidity of action is quite remarkable in comparison with that of ether and chloroform. Thus an 88 per cent. saturation of the blood occurs in the first five minutes of anaesthesia, and a complete saturation in seventeen minutes. In one minute after discontinuing administration 85 per cent. of the acetylene has been eliminated, and practically every trace has disappeared in from twenty to thirty minutes.

The patient's own carbon dioxide by rebreathing, or a carbon dioxide-oxygen (5 to 95 per cent.) mixture, may be used with due discretion to speed up both effects through stimulation of the respiratory function. Higher carbon dioxide-oxygen mixtures (30 to 70 per cent.) are being used to bring either induction, saturation, and elimination within the purview of gas-oxygen anaesthesia; and some anaesthetists are using spurts of 100 per cent. carbon dioxide for emergency stimulation. While this sort of thing may not involve too great a hazard with etherization, it has decided limitations and as yet uncharted dangers in connexion with gas-oxygen anaesthesia. Carbon dioxide has anaesthetic properties, and when used with nitrous oxide or the hydrocarbons in more than normal volumes both gases tend to displace oxygen, and they project the patient and anaesthetist into the unfathomed realms of three-gases physiology.

The rapidity of saturation and elimination of gas anaesthetics accomplish many important and valuable clinical results:

1. The actual duration of anaesthesia is very appreciably shortened in comparison with other methods.
2. Surgical relaxation may be more quickly secured (by secondary saturation or synergists) when desired; and as readily dissipated when no longer needed.
3. Recovery of consciousness and rational control are almost immediate, even after prolonged administration.
4. Bodily functions are scarcely interfered with, and pathological conditions are not aggravated.
5. By-effects of anaesthetic "hang-over" (headache, nausea, vomiting) are avoided or minimized.
6. Thirst may be quenched and nourishment taken very shortly after operation.
7. Anaesthesia may be repeated several times at brief intervals, or oftener at longer intervals.
8. The danger signs of overdose, oxygen want, or carbon dioxide depletion are conspicuous enough to give timely warning, and the leeway for resuscitation in emergencies is fairly wide. The heart is inclined to "carry on" after breathing becomes embarrassed or stopped, and the respiratory centre remains so responsive that often a moment or two of diffusion elimination by withdrawing the anaesthetic, or a few breaths of oxygen under pressure, or brief artificial respiration, suffice to restore vital functions.

Clinically nitrous oxide has been repeated for painful dressings on the same patient every day for more than a month without harmful effects. Ethylene is almost as innocuous. In a series of 1,000 acetylene cases 111 were anaesthetized twice; 45 three times; 6 four times; 3 five times; 2 six times; and 1 seven times within short intervals, often on the same or the next day, with apparently no extra hazard from the repetition (Sollbach).

Experimentally white rats, anaesthetized with propylene every day or so during a period of three or four months, have shown average growth, continued good health, and on being returned to their cages have borne litters of normal young. It is difficult to conceive of any form of

anaesthesia that would have less harmful biological effects than are indicated by these results with the gas anaesthetics (Lloyd K. Riggs).

In passing it might be mentioned that if gas anaesthetics could be given in pressure chambers under one-sixth of an added atmosphere, gas-oxygen anaesthesia would not only be surgically ideal, but also practically foolproof so far as safety is concerned. It has been shown that otherwise lethal doses of even propylene will not kill experimental animals in the pressure chamber in the presence of atmospheric volumes of oxygen (20 per cent.) (Paul Bert, Leonard Hill, J. T. Halsey).

Spectroscopic examinations of the blood under nitrous oxide, ethylene, acetylene, and propylene anaesthesia disclose no bands that would indicate any combination with haemoglobin. Suspicions of such a possible combination aroused by peculiar colour changes of the skin and blood may indicate specific effects of the gas anaesthetics themselves, or may indicate the presence of impurities (nitric oxide, carbon monoxide); or synergists (acetone, ether). Apparently the gas anaesthetics are merely in physical solution in the blood, and in addition are in some sort of transient solubility or diffusion in the lipoids.

#### *Bodily Functions.*

With ether and chloroform anaesthesia there is an immediate and marked lowering of the blood pH, leading to a condition of uncompensated alkali deficit. This may occur independently of respiratory variations, and may go on to profound acidosis (coma) if saturation is excessive and elimination delayed. Nitrous oxide-oxygen anaesthesia leads to an initial alkalaemia, followed by a tendency towards an acidemia; an acapnia plus an anoxic anoxaemia effect. Ethylene-oxygen with anoxaemia present gives the same results as nitrous oxide-oxygen; while ethylene-oxygen without anoxaemia causes a gradual lowering of the blood pH, but not beyond normal limits after forty minutes of anaesthesia. Acetylene-oxygen shows a slight tendency to acidosis if any anoxaemia is present, but its development is not nearly so rapid or marked as with ether, chloroform, or ethyl chloride. Similarly the blood pH under propylene remains within normal limits provided oxygen need is fully met and carbon dioxide depletion is avoided. This again stresses the vital importance of maximum oxygen percentage and controlled rebreathing in gas-oxygen anaesthesia.

Ether and chloroform produce a decided hyperglycaemia during anaesthesia, presumably by inhibiting the internal secretion of the pancreas and disturbing the glycogen function of the liver. Carbohydrate metabolism is thus perverted and a delayed form of acidosis (ketosis) results, which comes on in twenty-four to forty-eight hours after operation and accounts for much of the morbidity and mortality following these anaesthetics. Under nitrous oxide or ethylene-oxygen and the other gas anaesthetics there is an immediate but very mild hyperglycaemia and some formation of ketone bodies; but the entire disturbance of carbohydrate metabolism is of a very transient sort. Properly given the gas anaesthetics tend to increase or stabilize rather than decrease the carbon dioxide combining power of the blood (C. D. Leake).

Ether and chloroform anaesthesia, if at all deep and prolonged, readily lead to oliguria or anuria, especially in the presence of nephropathy or a tendency to kidney dysfunction, on account of the ketosis and the depression of the circulation they produce. On the contrary, the gas anaesthetics are so slightly irritant chemically, pervert acid-base equilibrium so little, and sustain blood-pressure so well, that even their prolonged use in the presence of nephropathy does not materially affect kidney function.

There is some complaint that gas anaesthetics increase haemorrhage, especially oozing from raw surfaces. It is difficult to account for this effect from any physico-chemical action of the gas anaesthetics on the blood stream, its constituents, or the circulation. In view of the fact that excess of oxygen and carbon dioxide both hastens clotting and reduces bleeding time, this objectionable feature complained of by some may actually result from the sort of gas-oxygen administration that steers a devious and vacillating course between the extremes of toxemia

DEC. 11, 1926]

## NEWER GAS ANAESTHETICS.

THE BRITISH  
MEDICAL JOURNAL 1111

and acapnia. That this effect need not be pronounced may be seen from the results in a series of 200 each normal, nitrous oxide, and ethylene labours, in which nitrous oxide in the newborn prolonged the average bleeding time one minute and the clotting time two minutes, while ethylene prolonged the average bleeding time two minutes and the coagulation time three minutes; but both times were back to normal in nine days (Sanford).

It is not surprising that internal hysterograms should show that ether and chloroform have an inhibiting effect on uterine contractions and that gas anaesthetics are more inclined to increase than decrease uterine contractions, while at the same time affording more definite and controllable pain relief and oxygenation. Even in the presence of eclampsia, toxæmia, nephritis, and cardiac decompensation the gas anaesthetics add the least burden to an already embarrassed mother and unborn babe. Gas-oxygen anaesthesia eliminates subinvolution (C. P. Rucker), haemorrhage as well as delayed involution and secondary

Of course, there is a time limit (usually two hours) beyond which no anaesthetic, even nitrous oxide, in clinical use may be relied on to maintain blood pressures; although in surface surgery in an otherwise healthy person the blood pressure levels may hold up well for three and four hours under the gas anaesthetics. Anoxæmia causes a rise of pressure levels may hold up well for three and four hours under the gas anaesthetics. If nitrous oxide is inclined to maintain its rate. With ethylene and acetylene the blood pressures and pulse rate may fall very slightly after surgical narcosis has been attained, and then remains stabilized for long periods, unless there is operative trauma, haemorrhage, or some systemic or pathological condition leading to shock. Under ordinary conditions the gas anaesthetics do not show the gradual circulatory depression that usually accompanies ether, chloroform, and ethyl chloride anaesthesia; and in the presence of shock, gas-oxygen anaesthesia has within itself and the technique of its administration remedial measures of incalculable efficiency (E. I. McKesson, John S. Lundy).

Apart from propylene and the higher members of the series, the other routine gas anaesthetics do not seem to have any specific effect on the heart so far as electrocardiographic studies show; and the gas anaesthetics have the least possible effect in exaggerating existing cardiac lesions during their administration. Various heart complications may occur under all anaesthetics (tachycardia, bradycardia, blocks of different kinds, myocardial failure, fibrillation), but such complications are certainly no more numerous under gas anaesthetics used for the anaesthetic cases than under ether, chloroform, and ethyl chloride, or the fact would be strikingly reflected in the gas anaesthetic death rates. Some have attempted to label the gas anaesthetics as especially dangerous for hysterectomy; and yet of a series of 11 fibroid cases only 2 died under anaesthesia, while 9 died tragic cardiac deaths while up and about or in bed awaiting operation. Myocardial degeneration and profound anaemias hold out an extra hazard to patients under all forms of anaesthesia; they are difficult to evaluate as to their reserve vitality, and their warning signs of danger are all too insignificant even to the expert anaesthetist. They account for many anaesthesia tragedies, and under gas-oxygen anaesthesia the mistake is usually made of expecting them to provide colour and blood pressure reactions which patients with these complications are unable to give.

The actual effects of various anaesthetics on the gastrointestinal tract may offer a clue to the comparative incidence of nausea and vomiting after anaesthesia, apart from any other factors involved. During the surgical stage of anaesthesia with ether or chloroform there is marked loss of tonus and almost complete inhibition of both rhythmic and peristaltic contractions in the stomach, small intestine, and colon. During the recovery period the stomach continues to show some degree of depression for an hour or longer. The small intestine develops recover more rapidly after stopping the anaesthetic and show increased activity. The small intestine develops exaggerated peristalsis, while the colon shows a marked increase in tonicity.

The relatively light surgical anaesthesia maintained with ethylene-oxygen causes no marked change in the activity of the gastro-intestinal tract. A slight increase in tonicity and amplitude of contraction has sometimes been observed. During the post-anaesthetic period also there is no marked change in muscular activity. A slight decrease in activity is often observed about an hour after anaesthesia.

Nitrous oxide-oxygen anaesthesia produces a marked increase in the size of contractions of the stomach, ileum, and colon in proportion to the anoxæmia present. On discontinuing the nitrous oxide-oxygen there promptly occurs a very marked inhibition of activity in these three portions of the gastro-intestinal tract; tone is lowered, peristalsis ceases, and segmental contractions are much diminished. This depression will usually last one hour or longer.

The effects of general anaesthesia on a denervated loop of ileum do not differ essentially from those observed on a loop with intact nerve supply, showing that the effects produced are due chiefly to an action on intrinsic structures (G. H. Miller).

With this résumé of some of the more basic comparative relations, characteristics, and effects of the gas anaesthetics, in the discussion that is to follow we may pass on to a more detailed consideration of their practical administration as well as their scope and utility in various operative procedures of surgery and the specialties.

### ADDENDUM BY E. I. MCKESSON, M.D.

By request, I shall elaborate Dr. McMechan's paper with regard to the differences in anaesthesia signs between nitrous oxide-oxygen and ethylene-oxygen. There are some outstanding differences between these two agents which should be understood, since a confusion of the signs may lead to embarrassment of the anaesthetist at times. The accompanying table (p. 1112) shows the usual signs indicating light, normal, and deep narcosis with this anaesthetic; a second chart shows the stages and signs of ethylene-oxygen anaesthesia as noted by John S. Lundy.

My experience with ethylene has been gained from the following technique. Induction has always been by nitrous oxide-oxygen, followed by ethylene-oxygen at any stage of the operation in which it has been considered desirable. But in no case is ethylene in my hands used throughout the narcosis. It is usually employed for a few minutes up to half an hour, returning to nitrous oxide-oxygen toward the close of the operation, that as much as possible of the ethylene may be eliminated during the narcosis under nitrous oxide-oxygen.

In major operations and in certain minor cases with complications, the pulse, respiration, blood pressures, tidal respiration, rebreathing, and the percentage of oxygen administered are all determined at frequent intervals and charted in a graphic manner. This is done routinely regardless of the anaesthetic employed. With this information at hand in a considerable number of cases it is rather easy to note the relative effects of the two anaesthetics. Ethylene resembles ether in many of its effects. It also resembles nitrous oxide in speed and is less irritating to the respiratory tract than ether, but more so than nitrous oxide. Hence it rarely induces a flow of mucus such as ether, but there is more moisture than with nitrous oxide. When ethylene is turned on after an induction with nitrous oxide-oxygen the patient almost never coughs, so that the sequence is easier and smoother than the nitrous oxide-oxygen-ether sequence.

The vomiting reflex with nitrous oxide in about 80 per cent. of cases in which it is a sign is due to deep anaesthesia and is corrected by increasing the percentage of oxygen in the mixture. Ethylene resembles ether in this, and blanching, swallowing, retching, and vomiting are usually due to light anaesthesia, which is corrected by increasing the ethylene percentage. Occasionally this complication prevents the substitution with nitrous oxide-oxygen at the close of the operation, which is an undesirable characteristic of ethylene. Vomiting is not always due to light anaesthesia with ethylene, since a case

## NITROUS OXIDE-OXYGEN SIGN CHART.—E. I. McKESON.

| LIGHT ANAESTHESIA.<br>Due to too much oxygen in the mixture.  | NORMAL ANAESTHESIA.<br>Due to a properly balanced mixture of $N_2O + O_2$ .  | PROFOUND ANAESTHESIA<br>Due to too much $N_2O + O_2$ in the mixture or to partial obstruction of respiratory passages.  |
|---|--|---|
| <b>RESPIRATION.</b><br>(a) Superficial slow breathing usually regular.<br>(b) Prolonged inspiration.<br>(c) Phonation due to reflexes or pain.<br>(d) Holding breath, grunting.     | <b>RESPIRATION.</b><br>(a) Full "machine-like" respirations. Regular and faster than normal.<br>(b) Inspiration and expiration nearly equal.<br>(c) No phonation.<br>(d) Continuous uninterrupted respiration. | <b>RESPIRATION.</b><br>(a) Irregular rhythm (sobby) usually slower than normal. Spasmodic.<br>(b) Prolonged expiration.<br>(c) Phonation due to muscular spasm of vocal cords. Often crowing.<br>(d) Cessation of respiration from spasm of muscles of exhalation.                        |
| <b>MUSCULAR PHENOMENA.</b><br>(a) Movement or rigid muscles.<br>(b) Facial expression of pain or consciousness.<br>(c) Nausea, very rarely.<br>(d) Reflex, or voluntary resistance. | <b>MUSCULAR PHENOMENA.</b><br>(a) Immobile and relaxed, but having normal muscular tonus.<br>(b) Expression of normal sleep.<br>(c) Quiet.<br>(d) Quiet. Relaxed.  | <b>MUSCULAR PHENOMENA.</b><br>(a) Clonic movements, twitching or jerking in early minutes of induction, often start in upper eyelids.<br>(b) Expression wild looking.<br>(c) Swallowing, retching or vomiting, common.<br>(d) Tetanic, spasm, marked rigidity—opisthotonos in some cases. |

Often wide open.  |
| <b>COLOUR IN SKIN.</b><br>(a) Pink or no change normally.<br>(b) In anaemics, no colour change.<br>(c) In plethorics, slight cyanosis.  | <b>COLOUR IN SKIN.</b><br>(a) Varies from pink to decided cyanotic tint.<br>(b) In anaemics, no colour change.<br>(c) In plethorics, considerable cyanosis.  | <b>COLOUR IN SKIN.</b><br>(a) Usually cyanotic.<br>(b) In anaemics, slight flushing, rarely cyanosis.<br>(c) In plethorics, almost black.   |
| <b>Remedy.</b><br>Decrease the percentage of oxygen in the mixture.   |  | <b>Remedy.</b><br>Increase oxygen in the mixture or in (d) inflate lungs with pure oxygen 1 to 3 times.   |

## SIGNS OF ANAESTHESIA WITH ETHYLENE AND OXYGEN.—JOHN S. LUNDY.

| A. WITHOUT MORPHINE.  | B. WITH MORPHINE.  |
|---|--|
| <b>First stage (40 to 60 seconds) 50 per cent. <math>C_2H_4</math> + 10 per cent. <math>O_2</math>.</b><br>1. Pupil normal, occasionally a sudden fleeting dilatation. Reacts quickly to light.<br>2. Skin pink.<br>3. Relaxation absent.<br>4. Eyeball moving freely.<br>5. Temperature of skin unchanged.<br>6. Humidity of skin unchanged.<br>7. Pulse rate often increased.<br>8. Blood pressure often about 20 mm. high or low.<br>9. Respiration voluntarily normal.<br>10. Blood pink. | <b>First stage (25 to 50 seconds) 85 per cent. <math>C_2H_4</math> + 15 per cent. <math>O_2</math>.</b><br>1. Pupil contracted. Reacts quickly to light.<br>2. Skin pink.<br>3. Relaxation slight or absent.<br>4. Eyeball moving freely.<br>5. Temperature of skin unchanged.<br>6. Humidity of skin unchanged.<br>7. Pulse rate normal.<br>8. Blood pressure normal.<br>9. Respiration voluntarily normal.<br>10. Blood pink.                  |
| <b>Second stage (light surgical anaesthesia, occasionally a period of excitement) 2 to 5 minutes, 85 per cent. <math>C_2H_4</math> + 15 per cent. <math>O_2</math>.</b><br>1. Pupil normal or slightly dilated. Reacts quickly to light.<br>2. Skin pink.<br>3. Relaxation moderate.<br>4. Eyeball moving.<br>5. Temperature of skin normal.<br>6. Skin dry.<br>7. Pulse rate usually normal.<br>8. Blood pressure usually normal.<br>9. Respiration deeper and faster.<br>10. Blood red.     | <b>Second stage (light surgical anaesthesia, usually no excitement) 2 to 3 minutes, 80 per cent. <math>C_2H_4</math> + 20 per cent. <math>O_2</math>.</b><br>1. Pupil contracted. Reacts to light.<br>2. Skin pink.<br>3. Relaxation moderate.<br>4. Eyeball moving slowly.<br>5. Skin normal.<br>6. Skin dry.<br>7. Pulse rate slightly increased.<br>8. Blood pressure normal or slightly lowered.<br>9. Respiration faster.<br>10. Blood red. |
| <b>Third stage (deep surgical anaesthesia) 5 to 15 minutes, 80 per cent. <math>C_2H_4</math> + 20 per cent. <math>O_2</math>.</b><br>1. Pupil slightly dilated. Reacts to light.<br>2. Skin pink.<br>3. Relaxation good.<br>4. Eyeball fixed, often turned and fixed.<br>5. Skin warm.<br>6. Skin dry.<br>7. Pulse rate normal or slowed.<br>8. Blood pressure normal or lowered.<br>9. Respiration normal as in sleep.<br>10. Blood pink.  | <b>Third stage (deep surgical anaesthesia) 3 to 10 minutes, 75 per cent. <math>C_2H_4</math> + 25 per cent. <math>O_2</math>.</b><br>1. Pupil normal. Reacts slowly to light.<br>2. Skin pink.<br>3. Relaxation very good.<br>4. Eyeball fixed, may be turned and fixed.<br>5. Skin warm.<br>6. Skin dry.<br>7. Pulse rate normal or slowed.<br>8. Blood pressure normal or lowered.<br>9. Respiration normal as in sleep.<br>10. Blood pink.    |
| <b>Fourth stage. Pre-mortem (at any time) 97 per cent. <math>C_2H_4</math> + 3 per cent. <math>O_2</math>.</b><br>1. Pupil dilated. Does not react to light.<br>2. Skin blue, black, and finally grey.<br>3. Relaxation complete.<br>4. Eyeball fixed.<br>5. Skin cold.<br>6. Skin moist.<br>7. Pulse rate fast, irregular and faint.<br>8. Blood pressure very low.<br>9. Respiration shallow, irregular and inhibited.<br>10. Blood black.  |  |

is now and then encountered in which this sign is corrected by increasing the oxygen percentage.

Ethylene usually resembles ether in its effects upon respiration; it slows the respiration progressively and reduces the tidal respiration as the narcosis is deepened, until it becomes inefficient and stops. Nitrous oxide usually increases the rate and amplitude of respiration as narcosis is deepened until a clean-cut sharp crisis occurs in deep narcosis which is followed by slow, more or less inefficient respiration and apnoea.

The sudden change or crisis is less frequently seen in ethylene, and for this reason is not as safe as nitrous oxide in the hands of the inexperienced. On the other hand, ethylene, in a small percentage of cases, causes rapid instead of slow respiration, and in these cases it does not appear to be as suitable for the patient as nitrous oxide. In changing from nitrous oxide-oxygen to ethylene-oxygen we should expect the respirations to become slower, more regular, and smaller, and it is for this purpose that it is used in some of my cases. If it fails to accomplish this result it is usually turned off.

When producing a slow "secondary saturation" with ethylene-oxygen, if respiration ceases more time is required to resuscitate with oxygen forced into the lungs, which is a disadvantage as compared with nitrous oxide. Perhaps this is due to the more complete fixation of this gas by the lipoids, or it may be caused by the slower circulation in removing the excess of gas from the tissues; finally, some impurity such as carbon monoxide in the gas may be responsible. This peculiarity, however, is not of such magnitude as to prevent its use in producing deep narcosis, providing an apparatus is employed that is dependable for artificial respiration with oxygen by the inflation method.

Ethylene-oxygen in about half of the cases produces a slower pulse by about ten beats a minute than nitrous oxide-oxygen. Sometimes the slowing amounts to a bradycardia. Those cases with a slow pulse seem to do best under its influence. In other cases the pulse rate increases over that of nitrous oxide-oxygen, and these often show a marked fall in blood pressures, resembling shock. In the bradycardia cases the blood pressures may fall somewhat, but not out of proportion unless the blood is being overdosed, which may be quickly determined by a few breaths of oxygen of higher percentage.

The blood pressures under nitrous oxide-oxygen are variable with the depth of anaesthesia, trauma, blood loss, etc., but under normal conditions tend to remain within normal limits. The usual result of ethylene-oxygen is a fall in blood pressure similar to ether after the stage of induction. Time will not permit a full discussion of pulse-blood pressure ratios.

The eye signs, particularly the pupil, are more sluggish and unreliable under ethylene than with nitrous oxide-oxygen. However, deep narcosis usually causes a dilatation of the iris. But when it occurs it is not as promptly remedied by the administration of oxygen as it is after nitrous oxide-oxygen. There is less oscillation of the globes with ethylene.

Ethylene is often used to secure a greater degree of muscular relaxation. While this is usually easier to secure with it than with nitrous oxide-oxygen, cases are not infrequently seen in which nitrous oxide-oxygen is better. When high concentrations of ethylene are necessary to secure relaxation, anoxaemia frequently prevents it, and in these cases recourse may be had to nitrous oxide or other procedures, such as premedication or ether. My use of ether for this purpose is indeed rare. In 1925 ether was not used in a single case. This year it has been used in five or six cases for various reasons.

Ethylene, like nitrous oxide, co-ordinates well with morphine-hyoscine premedication. Occasionally atropine is administered during the narcosis for bradycardia, but never as a routine. We use from 1/6 to 1/3 grain of morphine, usually 1/4 grain in adults, and never more than 1/100 grain of hyoscine.

Cyanosis of some degree is not infrequent in the use of nitrous oxide-oxygen. This is most marked in the early minutes of narcosis while saturation is in process. Later in the narcosis, cyanosis is usually absent or of slight

degree. Cyanosis is not a sign of anaesthesia, hence it cannot be relied upon. In ethylene-oxygen anaesthesia cyanosis is not as frequently seen, nor is it the pure cyanosis of anoxaemia seen in nitrous oxide anaesthesia, but an *ashy hue* associated with a more precarious state of the patient when it occurs.

Blanching or paleness with ethylene is usually due to nausea. Whether the colour of the blood and skin in ethylene anaesthesia is lighter, due to some action upon the haemoglobin or to a greater decrease in general metabolism or to some impurity or contamination of the gas such as carbon monoxide, is not yet established. But it may be due to all three or any one of the three in a given case. For myself, I prefer to use ethylene, not as a routine, but on indication for some desired pharmacological action, the same as one would employ morphine, hyoscine, atropine, digitalis, ether, etc., relying upon nitrous oxide-oxygen as the basic anaesthetic.

It appears from the signs that ethylene is more depressing and powerful generally than nitrous oxide.

H.—E. I. McKESSON, M.D.,  
Toledo, Ohio, U.S.A.

#### SOME PHYSICAL FACTORS IN THE ADMINISTRATION OF GASEOUS ANAESTHETICS.

A DISCUSSION of this subject may be warranted by the fact that modern anaesthesia is a mechanical application of many of the laws of physiology, physics, and chemistry. An appreciation of the purposes and mechanism of anaesthesia as well as an understanding of the problems of administration comprises about half of the science of anaesthetics, while much of the art may be credited to the apparatus with which to meet the problems in technique and to accomplish these purposes.

In every nitrous oxide-oxygen or ethylene-oxygen anaesthetic the anaesthetist must apply certain, if not all, of those basic principles of administration through which the science and art have evolved up to the present time. A discussion of these factors, therefore, may be helpful in a field not too well understood.

#### Mechanism of Anaesthesia.

The anaesthetist alters the gaseous content of the tissues to effect a reduction of oxidation or metabolism in certain of the more highly specialized nervous tissue without similarly affecting the metabolism of other tissues. This is probably the result, mainly, of a singular combination of (1) solubilities of gases in the body fluids, (2) the difference in oxygen requirements of the several tissues, (3) together with an absence of chemical change of the anaesthetic gas while in the body. The solubilities and oxygen requirements are of paramount importance to the anaesthetist.

#### Solubility of Gases in Body Fluids.

When one considers the transport of gases from the lungs to the tissue cells, or particularly the nuclei, he thinks first of the blood and the carrying power of haemoglobin for oxygen. However, the haemoglobin goes only part way, since it does not actually come into contact with cells outside the blood vessels. And although whole blood carries from 18.5 to 20 volumes per cent. of oxygen, the brain cell, for example, must obtain its oxygen through the plasma, lymph, and finally the cell juices within its own membrane, quite separate from the haemoglobin. Since the plasma carries but 0.24 per cent. O<sub>2</sub> normally, the brain cell must live in a solution containing not more, but undoubtedly less, than this percentage. The haemoglobin, therefore, acts as a store of highly concentrated oxygen, which is liberated or dissociated from the haemoglobin as the tension of oxygen is reduced in the fluids bathing the cell and the red corpuscle. This is an important point for the anaesthetist to keep in mind if he is to visualize what probably takes place in narcosis. The plasma also carries 1.7 per cent. of nitrogen derived from the air inhaled. It is not metabolized as is oxygen.

The amount of a gas which a liquid will absorb depends upon the character of the gas as well as the liquid and its temperature. Although we breathe about 80 per cent. nitrogen in the air, only 1.7 per cent. is dissolved in the plasma; likewise, we inhale almost 20 per cent.  $O_2$ , yet the blood plasma dissolves only 0.24 per cent. The brain cell obtains its oxygen from a liquid where the ratio of  $N_2$  and  $O_2$  is roughly as 7:1. Carbon dioxide also plays an important role, but it will be disregarded for the present.

"From the standpoint of physical chemistry the partial pressure of a gas in solution is simply the vapour pressure of the dissolved gas."<sup>1</sup> When nitrous oxide is inhaled it diffuses as if the whole body were a liquid in which it was soluble up to a certain tension. Hence it is not so remarkable that more than one litre a minute of this gas is absorbed upon induction. Paul Bert fixed the solubility of nitrous oxide in blood as 45 volumes per cent. This was *in vitro*. Greene<sup>2</sup> has shown that, *in vivo*, anaesthesia is secured in the dog when 26 volumes per cent. are dissolved; that is to say, nitrous oxide is fifteen times more soluble than nitrogen and one hundred times greater than oxygen in the blood plasma, since there is no proof that this gas is carried by the haemoglobin in chemical combination. The ratio of seven molecules of  $N_2$  to one molecule of  $O_2$  is compatible with normal physiology, but when one hundred molecules of  $N_2O$  to one of  $O_2$  are present anaesthesia results.

#### *Oxygen Requirements for Different Tissues.*

Anaesthesia, then, may be due to the dilution or dispersion of the  $O_2$  molecules so that certain cells are unable to find enough oxygen with which to maintain metabolism or chemical activity up to the usual rate; that is, oxygen want or anoxaemia may interrupt such functions as depend upon a maximum oxygen supply. In support of this view the researches of Taschiro<sup>3</sup> show that nervous tissue metabolizes more rapidly, therefore requires a more liberal supply of oxygen molecules, than other tissues. G. H. Parker's<sup>4</sup> investigation of metabolism of dogfish nerve also substantiates certain of Taschiro's findings in this particular.

Upon these grounds it may be assumed that at certain tensions of  $N_2O$  and  $O_2$  in the body juices the activity of certain nerve cells is curtailed, while other cells, such as those of muscle and the more ancient and stable nerve tissue, may find sufficient oxygen for their usual functions unabridged.

Now since the amount of gases which a given volume of liquid will carry in simple solution depends with other things upon the proportions or tensions of these gases in contact with the liquid, the mixture of gases inhaled is the most important determining factor of the tensions of these gases held in solution. Hence the tensions or proportions of the inhaled gases determine the depth of anaesthesia.

Since nitrogen is less soluble than nitrous oxide, it interferes with the production of anaesthesia and must therefore be excluded as far as possible from the gases inhaled. The first requisite to nitrous oxide-oxygen anaesthesia is the exclusion of air. The second is the production and maintenance of the proper proportions of nitrous oxide and oxygen. The variation in mixture compatible with deep anaesthesia is very small indeed. Often as little as 1 per cent. perceptibly alters the depth of narcosis.

Within narrow limits, the chemical adjustments of the patient are extremely flexible, producing certain signs by which the anaesthetist may be guided in the adjustment of the various mechanical elements of control. So important are these mechanical factors in this form of anaesthesia that the best qualified anaesthetist is unable to overcome some of the handicaps of a faulty apparatus and at the same time secure the best results. On the other hand, the tyro with his limited knowledge is unable to utilize fully the factors of control which may be embodied in a well designed instrument.

It is the purpose now to discuss the physical problems of administration which confront every anaesthetist, and to review briefly some of the mechanical methods which have been devised to assist him.

#### *Functions of the Apparatus.*

There are four outstanding functions for an anaesthetizing apparatus. The first of these comprises suitable inhalers, connexions, valves, etc., for the exclusion of air. The second embodies positive control of the mixture of gases to be administered. The third is represented in the control of the pressure of mixed gases in the inhaler. The fourth is the regulation of rebreathing. A fifth might be added as an accessory of great clinical importance—namely, a mechanism for artificial respiration by inflating the lungs with oxygen.

#### *Mixture Regulation.*

The depth of anaesthesia is controlled by the proportion of oxygen and nitrous oxide contained in the mixture, and since this ratio for the ordinary patient is very definite, the means for regulating the mixture was an important problem in the development of this anaesthetic.

Early in the experimental stages some fixed and known mixture was sought by Hewett and others which might produce narcosis. But it was soon learned that no single mixture could be depended upon for all subjects, nor, in fact, for the same patient at different periods in the operation. The necessity of altering the mixture from time to time made some adjustable mixing apparatus essential. The problem therefore became more complicated, and has consumed years of experimentation in reaching its present state of development.

Hewett and others early resorted to rubber bags as containers and a valve between them to proportion the two gases, but owing to the inability of the anaesthetist to keep the two bags equally filled—that is, to maintain equal pressures in the bags by manual control of valves—the mixture varied so widely that a smooth narcosis by this method was often impossible for long periods.

Mixing two gases in proportions sufficiently accurate to maintain narcosis has been a very difficult procedure to carry out over a long period. There are several reasons. First, gases are composed of rapidly moving molecules with a vacuum between them, resulting in a most mobile body. Secondly, owing to this great mobility, and also to the exceedingly rapid absorption of these molecules by the blood, the effect of any change in the proportions of these two kinds of molecules is quickly reflected in the depth of narcosis.

According to Avogadro's law, that equal volumes of gases with the same pressure and temperature contain an equal number of molecules, and since 1 c.cm. of a gas at  $0^\circ C.$  and 760 mm. Hg contains about 27 trillion molecules, relatively slight changes in temperature or pressure of one of the gases produce tremendous changes in the number of molecules in a given volume of the gas. Again, at any stated temperature a given mass of gas varies in volume inversely as the pressure (Boyle's law). Hence great changes in the depth of narcosis follow any rather slight alteration in these physical conditions of either gas as it passes through the mixing device.

When the gases are drawn from their high-pressure containers both the temperature and the pressure vary. In some machines used in administration the pressure has been the greater source of error, in others the temperature variations. So difficult of control and elusive were these gases under slight differences of pressure that many anaesthetists came to the erroneous conclusion that the gases themselves were inefficient for protracted anaesthesia, and therefore ether in sufficient amounts was vaporized into the mixture to complete narcosis. It is now known, however, that the ether thus administered largely functioned either by compensating for the errors of fluctuations in the mixture or by becoming the dominant agent. But it has been demonstrated in practice for several years past that nitrous oxide-oxygen may be successfully administered for any operation without ether, if the mixture and certain other factors are properly controlled. Gradually these facts became known, and more serious efforts were made to devise some apparatus which might produce and maintain the desired mixtures.

*The Continuous Flow Appliances.*

Twenty years ago it was thought by some anaesthetists that the best way to produce and maintain the mixture for clinical work was to flow the two gases together continuously and uniformly, varying the proportions usually by adjusting the flow rate of the oxygen. This, however, failed at once, since the nitrous oxide tank valve could not be made to deliver this gas uniformly because of freezing, and also because of a progressive fall of pressure in the tank as it was used. Likewise the oxygen varied, although in practice it did not freeze. To overcome this difficulty, a few years later a pressure-reducing valve or regulator was interposed between the tank and mixing apparatus proper, so that the falling pressure in the tank might not so greatly influence the delivery rate. This marked some advance in the evolution of the anaesthetic, but was not completely successful because, however carefully the regulator had been constructed, it was still subject to relatively large variations of pressure and delivery rate when applied to gases for this purpose. Moreover, the very small apertures through which the gases were delivered often became more or less obstructed by small particles of water, ice, or foreign matter, or by changes in temperature, and the mixtures varied accordingly between limits quite incompatible with smooth narcosis.

It seemed that the system followed until that time (sixteen years ago) could not be made sufficiently dependable to warrant the use of nitrous oxide-oxygen for all operations unless some more practical instrument for mixing were devised.

*The Intermittent Flow Method.*

After considerable clinical experience with various forms of mixing apparatus then available, I experimented along another line. The mechanical problem presented many difficulties, but it appeared that if the nitrous oxide and the oxygen bags could be kept equally filled or under equal but very low pressure by some automatic bag-filling mechanism, progress might be made. After several trials, such valves were perfected which automatically replenished the oxygen and the nitrous oxide bags at each breath—stopping the flow from the tanks into the bags while the patient exhaled and paused between breaths. The bags were thus kept equally filled with their respective gases, regardless of the rate or volume of respirations.

Rubber bags are not of uniform thickness or weight, however carefully made; hence the two bags were placed together in a sack of fish net so that any, even very slight, differences of pressure of the two gases within the bags would be equalized by their walls pressing against each other. The pressure in the two bags was then always equal, regardless of what that pressure might have been.

Instead of a continuous flow apparatus this became an intermittent flow device. Certain advantages, however, resulted, among which were a foundation for proper mixture control and relief from attempts at manually adjusting the rate of flow, since the respirations regulated this function much better than the anaesthetist had done before. The possible range of automatic gas delivery was enormous—from nothing to more than 33 gallons a minute, so that no patient could exhaust the supply, however rapidly he breathed. The intermittent flow principle also adapted itself to the technique for intermittent administration in producing analgesia for obstetrics.

Hewett's two bags having a common rubber partition was probably not an attempt to equalize pressures, as there is no such purpose found in the literature, and they certainly could not have so functioned. Levy's recent plan of putting a small oxygen bag within the nitrous oxide bag could have been effective in a limited way had it been possible to see when it was empty or how much oxygen to add to refill it properly.

With the two gases in separate bags but kept at equal pressures the first factor in producing the desired mixture was then satisfied and the construction of a suitable mixing valve mechanism was undertaken. It was necessary in constructing the mixing mechanism to prevent any backward flow of mixed gases into either of the two supply bags during exhalations as well as any flow of gas from one bag into the other. This was accomplished by two check

valves placed over the outlets from these bags. It was also necessary that these check valves should open simultaneously; this was at first accomplished by fastening the check valves or discs together by means of arms on a shaft. Later, a single check or disc accomplished the same purpose when the two outlets were brought closer together. Between the bags and the check valves two plug valves were disposed—one for nitrous oxide, the other for oxygen—with rectangular openings piercing each and graduations on their heads indicating the degree of opening. Later these two valves were combined in one, since it was more convenient and accurate to adjust one valve than two.

The areas of the mixing ports were each made equal to the cross-section of the adult trachea, so that the velocity of gas through either or both of these ports was the same as that in the trachea. This latter type of mixing valve was provided with a partition, while the single check valve referred to closed the communication between the bags. When the latter was lifted during inhalations it uncovered the exits from the two bags through which the two gases passed in those proportions for which the mixing ports had been set. On top of this mixing valve was a graduated dial, indicating the degree of opening of each port. By turning this valve to one point nitrous oxide only was obtained, at another point pure oxygen was delivered, while at the several graduations between these two points any desired mixture was available. This was a convenient arrangement in practice, since this single adjustment regulated the mixture with the least possible effort and in the shortest time. Another section of the dial was graduated for mixtures of air and nitrous oxide, sometimes used in producing analgesia.

The mixed gas was conducted to the inhalers through a wide-bore flexible and non-collapsible rubber tube, making for easy inhalation. Between the mixing valve and the lungs was a volume of mixed gas equal to about two breaths, so that after the mixing valve had been set for any new proportion the effects of this new mixture were observed by the corresponding change in depth of anaesthesia about seven seconds later. This feature meant easier and more immediate control of the narcosis than was afforded when a large mass of mixed gas had to be converted into some new mixture.

Owing to the large size of the mixing ports, the differences in density between nitrous oxide and oxygen or between ethylene and oxygen did not introduce appreciable errors from their actions in accordance with Graham's law, nor did they permit small particles of foreign matter appreciably to obstruct or restrict the flow of gases from the two bags so as to affect the mixture. With the large bags as the immediate source of the supply of gases for mixing, the temperatures were practically equal, minimizing the effects of disturbances from their action in accordance with Boyle's law.

With that combination of elements a mixing mechanism resulted which was extremely sensitive and convenient for clinical work, not only in producing but also in maintaining the desired proportions for an indefinite period. The slightest change in position of the mixing valve alone resulted in a prompt and corresponding change in the depth of anaesthesia. It was responsive to less than 1 per cent., and hence met the preciseness of body demands by an equal accuracy of mixture control.

In addition to the advantages resulting from the intermittent flow principle enumerated, still another unexpected one followed. Whereas freezing of the nitrous oxide either at the tank valve or the regulator nozzle had been a common difficulty in continuous flow appliances, the opening and closing of the valves in synchronism with respiration under the intermittent flow principle caused the ice to be fractured and crushed with each breath, ensuring an adequate delivery of this gas into the bag under ordinary conditions. It also reduced the waste of gases, and thus further lessened the refrigeration in the regulator. Hence artificial heat by means of lamps, electric warmers, etc., was not required, except occasionally in slow tonsil operations, when a rubber bottle filled with hot water placed on the regulator sufficed.

With this apparatus the head of pressure back of the automatic bag-filling valves might fluctuate widely without

altering the mixture so long as there was enough pressure to cause the bags to refill before the next breath was taken, since the mixture is made from the bags and not from the regulators direct. In all continuous flow devices the mixture is always altered by any fluctuation of pressure back of the mixing device. In such devices efforts have been made to eliminate any (although slight) tendencies to freezing by the use of heaters, and more recently by drying the gas before compressing it into tanks. Efforts have also been made to construct regulators which might maintain an exact low pressure, but such have not yet been produced.

More recently, particularly in America, further experiments with continuous flow regulation of mixture have been attempted. Without eliminating the errors enumerated before, other sources of inaccuracy have been introduced in passing gases through very small orifices under variable heads of pressure and with other variable back pressures against the outlets of these orifices. One group employed water columns as indicating the head of pressure used to force gas through very small apertures. In one machine of this group,<sup>6</sup> the glass tubes were graduated in percentages. In another<sup>7</sup> they were graduated in the volume flow for each gas in litres per minute. These water type gas meters as produced excluded the successful employment of nitrous oxide-oxygen for certain operations owing to their limited range of delivery rates, and their use led many to the conclusion that nitrous oxide-oxygen might not be employed in certain operations.

#### *Effusion of Gases through Small Orifices.*

In passing gases through very small orifices (unobstructed by water, ice, or particles of foreign matter) such as were used in continuous flow mixing devices, at a given temperature and pressure the rate of effusion varies inversely as the square root of their densities (Graham's law). Compared with air, the density of oxygen is 1.105 and the square root is 1.049; the density of nitrous oxide is 1.522, the square root is 1.233. Then since they vary inversely, the oxygen would flow at the rate of 1.233 through an aperture which would deliver but 1.049 of nitrous oxide—a difference of 15 per cent.

In drilling very small holes through metal it is impracticable in manufacturing to reproduce such orifices; hence, if accurate, each meter had to be calibrated individually, which was not done. Furthermore, the thickness of the metal usually varies, which adds a variable error of wall friction to the passage of gases along the sides of the tiny tube. Gas analysis as well as clinical observation showed neither method to be within that range of accuracy necessary for the best work in nitrous oxide-oxygen anaesthesia, nor to afford other desirable features in an apparatus for clinical use. Similarly ethylene has a density of 0.969, and, although the difference would be less, the error was in favour of ethylene instead of oxygen.

In another group<sup>8</sup> spring gauges of the Bourdon type were employed. The oxygen gauge, instead of indicating pressure, was calibrated in percentages. The aperture for the oxygen was exceedingly small (71 drill, or about the size of the hole in a hypodermic needle), hence it was frequently more or less obstructed by foreign matter, so that the gauge indications of percentage were often erroneous. Such gauges are not to be depended on for extreme accuracy for any length of time. The nitrous oxide orifice was larger, but the pressure as indicated by its gauge was to have remained constant. In practice this was rarely possible owing to the variations in tank pressure, freezing, and alterations in the rate of delivery for which the apparatus was adjusted from time to time. In the design of this apparatus it was also assumed that by moving a plate of metal toward and away from these two orifices the rate of delivery of the two gases might be decreased or increased without altering the proportions as previously obtained. In practice and by gas analysis this was found not to be true, but, on the contrary, as the rate of the mixture delivered was increased the proportion of oxygen progressively decreased.

#### *Pressure in the Inhaler.*

Until the gases were delivered into the inhaler considerably above atmospheric pressure anaesthesia could not be

maintained for prolonged periods with nitrous oxide-oxygen for certain operations, such as the extraction of teeth, plastic mouth surgery, tonsillectomy, nasal operations, tracheotomy, operations upon the larynx, etc., because the patient inhaled too much air through the open air passage during the operation. Many, in fact, most, anaesthetics at some period of the operation are also improved by added pressure in the inhaler. Again, operations upon the neck often interfere with breathing unless inspiration is assisted by pressure; this is particularly true in some goitre cases. Then again, in thoracic surgery, pressure often is the factor which determines the success of the operation and the outcome of the patient, since collapse of the lungs may cause immediate death. Pressure also increases the absorption of the gases by the blood according to the laws of the solution of gases.

In order to manage such cases it is not only necessary to have pressure which is variable at the will of the anaesthetist, but at the same time the desired proportions of the gases must be maintained. It was the want of this dual control which, until recent years, precluded the use of nitrous oxide in this large group of cases and often embarrassed the anaesthetist in other cases.

In America Teter<sup>9</sup> successfully managed some of these types of operations by restricting the exit of gases from the inhaler while permitting the gases to flow continuously from the tanks into the apparatus. His production of pressure was not at the source but rather at the outlet of the apparatus. His was, therefore, *indirect*, and with any obstruction to the exit of gas through the mouth, such as occurs when the tongue is pushed back by the surgeon, the pressure progressively increased beyond the desired amount. Bags were occasionally ruptured when the supply was not promptly shut off. On the other hand, if the patient began to breathe more rapidly, exhaling through the mouth as in extractions or tonsillectomy, the pressure fell until the patient was able to draw air through the mouth, with the resultant light anaesthesia and occasionally the interruption of the operation. To offset this latter condition it was necessary to increase the rate of flow of the two gases in an effort to maintain the desired pressure. These were constant causes of adjustment and annoyance and a source of uneven narcosis, since the surgeon's necessary manipulations affected the patency of the air passages at frequent intervals. To provide a "blow off" valve to prevent excessive pressure was not permissible because of waste. What applied to Teter's method also applied to all other continuous flow appliances which followed it.

Pressure and flow rate are, therefore, not synonymous, but fundamentally different. Pressure control is the essential factor in these cases. It was recognized that what was needed was some *direct means for simultaneously varying the pressure of both gases* before they were mixed, and thus regulating the pressure itself by automatically varying the rate of flow from the tanks to maintain, but not to exceed, the desired pressure, whether that rate of flow be great or small.

#### *Pressure by the Direct Method.*

I tried several methods with his mixing device, such as tightening the net enclosing the bags and adjusting the bag-filling valves so that they distended the bags more tightly, but the desired result was obtained more simply when a spring and adjusting screw was attached to the automatic bag-filling valves. With this spring set at any desired tension (from 0 to 20 mm. Hg) it kept these valves open until the pressure in the two bags was great enough to overcome the spring tension and either to close the valves or decrease the flow of gases, according as the respiratory requirements of the patient might demand. Although the pressures delivered into the inhaler were subject to change by tightening or loosening the spring, the depth of narcosis was not materially disturbed because the pressures in the bags, whether great or small, were always equal.

This direct method for securing the pressure in the inhaler has worked well. The pressure has enabled the amount of gas admitted into the bags to maintain itself. This function is greatly appreciated when it is desired to

assist respiration by a little pressure without increasing the consumption of gas or causing unnecessary waste. The method has added much to the success and safety of gaseous anaesthetics. It has improved a large field of surgery involving the respiratory tract which was not only difficult for the surgeon and anaesthetist, but also more dangerous for the patient.

#### Rebreathing.

Rebreathing was employed in the earliest administrations of nitrous oxide. Then came a period of years when it was not considered safe; this was followed by a revival in the present period, in which it has been employed upon physiological grounds.

When Gatch revived rebreathing in 1910 it was practised as before, by manually filling a large bag with nitrous oxide and oxygen in which the patient breathed to and fro for some minutes; then the contents were exhaled from the apparatus and the bag was refilled with a new charge of gases from the tanks, and the procedure repeated. This method was immediately followed by two other methods—first the continuous flow method in which the nitrous oxide and oxygen flowed continuously into a bag, larger in volume than the tidal respiration, into and out of which the patient respired, expelling gas from the exhaling valve at irregular intervals depending upon the character of breathing.

#### Fractional Rebreathing.

Following the continuous method which was employed by me for a short time in a modified form, I devised the fractional method in 1910<sup>18</sup> upon the premises that, if rebreathing was to be employed, it should be done accurately to learn what, if any, advantages might accrue from its use other than the conservation of gases. Accordingly a small cylindrical bag, adjustable in capacity and calibrated in cubic centimetres, was constructed. With it the patient's tidal respiration was actually measured to determine if rebreathing were advisable, and then the bag was readjusted to hold any measured volume of exhalation for re-inhalation at each succeeding inspiration.

A variable measured portion of each inhalation thus consisted of previously exhaled gas, and the balance of inspiration was composed of fresh or previously unused gases from the mixing mechanism. It co-ordinated well with the intermittent flow principle.

With this fractional rebreathing it was soon evident that conservation of gas by rebreathing was of secondary importance and that its real value consisted in controlling more accurately the depth of breathing by the restricted elimination of CO<sub>2</sub>. It has afforded the anaesthetist an interesting study of the physiology of respiration under anaesthesia and added a certain finesse of control in correcting respiratory irregularities which has materially aided in the maintenance of deep anaesthesia.

Inhalers and other accessory equipment, although important in adapting gaseous anaesthetics to various operations, will not be discussed, but it is important that a few words should be added regarding oxygen insufflation.

#### Artificial Respiration with Oxygen.

The rapid action of nitrous oxide or ethylene—for they are administered in essentially the same manner and act much alike as to speed—requires careful watching lest the patient be crowded into apnoea. It was for this reason that I first incorporated a means for inflating the lungs with oxygen to re-establish respiration should it fail or threaten to stop. The mechanism incorporated in the apparatus described consists of a special valve which short-circuits the oxygen bag and delivers the oxygen through the inhaler and directly into the lungs. This arrangement was employed because bags would not withstand the necessary pressure to inflate the lungs under certain conditions. And to put oxygen into the lungs promptly and positively was essential.

It was demonstrated that the human lungs were in no danger of overdistension with oxygen, since the inhaler could not be so held even by force until a pressure of 80 mm. Hg might be developed. The dog's lungs will withstand more than 120 mm. Hg without rupture even with the chest open. Moreover, when properly performed,

the oxygen but partly fills the lungs at each inflation, developing little or no pressure therein, and when done at once one or two inflations usually restore the patient to a state of respiration. Hence this method was both effective and perfectly safe, and has proved to be so during many years of clinical use in which many lives have been saved.

When foreign bodies have been inhaled, such as vomited meat, tonsil or blood, gauze or cotton packs, and obstruct or interrupt respiration, a serious situation at once results. With ample oxygen pressure to pass the obstruction and to inflate the lungs, however, one is able to restore the cough reflex in a few moments, which assists in the expulsion of the material from the air passages.<sup>11</sup> Thus the lives of such patients, which were frequently lost by older methods of resuscitation, are now commonly saved by this procedure. Its availability at the moment and under proper control makes oxygen the ideal agent for the purpose—in fact, superior to any other.

#### CONCLUSIONS.

In conclusion it may be said that the physical factors in the administration of gaseous anaesthetics have been discovered and appliances have been devised for their successful application. The most important of these factors are:

1. Suitable inhalers for excluding air.
2. Regulation of the mixture of gases with means for maintaining any desired mixture.
3. The direct control and maintenance of pressure above that of the atmosphere, when required, without exceeding the safe pressure desired and also without unnecessary waste of gases.
4. Means for measuring the tidal respiration, and estimating the patient's ventilation to determine the need for rebreathing. Also means for rebreathing any desired measured volume of each exhalation.
5. Means for performing artificial respiration with oxygen by inflation as an integral part of the apparatus.

The intermittent flow principle co-ordinates well the above essentials for an anaesthetizing apparatus.

#### GENERAL DISCUSSION.

Dr. S. R. WILSON (Manchester) said he had not much sympathy with the electro-chemical theory of anaesthesia, but thought the metabolic theory deserving of careful consideration by all those interested in the newer anaesthetics. Hibernating animals showed the Cheyne-Stokes and Biot types of respiration, and there would appear to be a distinct relation between hibernating animals, the trance conditions of Indian fakirs, hypnosis, and anaesthetic conditions. As regards the newer gases, he wished to be sure of their superiority in many ways to nitrous oxide. It was difficult to be sure of the purity of the new gases, and it was necessary to be certain that they were in fact pure. The colour of the blood could not be relied upon to prove the anoxaemic condition of the blood, since ethylene gave similar results to carbon monoxide. Propylene was definitely out of court, and acetylene had the disadvantage of being explosive and difficult of purification. Dr. Wilson agreed with Dr. McKesson as to the desirability of ethylene in the case of the very old, the very young, and diabetics, but asked whether the normal slowing of the pulse with ethylene occurred in cases of exophthalmic goitre, where it would be a distinct advantage.

Dr. L. L. GREENBLUM (Akron, Ohio) emphasized the necessity of co-operation between the surgeon and the anaesthetist.

Dr. McMECHAN, in reply, stated that the interpretation of phenomena depended a great deal upon the occupation of the interpreter: the physiologist spoke from the physiological standpoint, the physicist from the physical. The duty of the anaesthetist was to seek out those who were doing and discovering things, and to bring forward their views without attempting to say which were correct in theory. Nitrous oxide and oxygen as an anaesthetic suffered from one basic fault in that everyone imagined that satisfactory anaesthesia could be secured by this means without adequate preparation. It was necessary for the patient to be receptive of the gas type of anaesthesia—he must have a blood stream capable of receiving and using the gas supplied. The anaesthetist must know the metabolism of the patient. Patients with myocardial degeneration could not stand anoxaemia, hence nitrous oxide and oxygen might fail. But if these patients were treated with digitaline they would do quite well with this type of anaesthetic. Toxaemic and septic cases were more difficult to anaesthetize with nitrous oxide and oxygen, and the same held true of those suffering from acidosis and ketosis. The purity of the nitrous oxide also made a difference—as, for example, when there was only a 1 per cent. leeway in administration. Controlled rebreathing, correct pressure, and correct method of administration were also necessary so that the patient's metabolism could be controlled. The problem for the anaesthetist to-day was to realize that it was impossible to give an anaesthetic well without knowing the basic signs of the physiology of gases in the blood.

Dr. McKESSON, in reply, said that unfortunately ethylene did not slow the pulse in cases of exophthalmic goitre. In these cases he reduced the metabolism before operation by test and morphine. A 10 per cent. reduction of metabolism could be effected by a quarter of a grain dose of morphine. The metabolic theory if applied in clinical work would certainly help. In Toledo both nitrous oxide and oxygen and ethylene and oxygen were being extensively used. In 1925 he personally had not used ether in a single case, and at the Lucas County Hospital one or other of the above anaesthetics had been used in 94 per cent. of cases. This year he had used ether five or six times only.

### MEDICAL, SURGICAL, OBSTETRICAL.

#### RECOVERY AFTER MASSAGE OF THE HEART.

IN the JOURNAL of August 28th (p. 404) Dr. Sainsbury has replied to a criticism that was made regarding the chief agent in the recovery of a patient when heart massage and adrenaline injections are combined. In Mr. Glover's note on this subject (JOURNAL, August 21st, p. 342) a case appears to have been resuscitated by heart massage alone, and I now wish to give an instance where adrenaline succeeded in causing contraction of the heart muscle when massage failed. It is not an instance of either agency being successful in restoring life, but I thought it interesting from the point of view of the comparative values of heart massage and the injection of adrenaline.

The case, which was a desperate one from the first, was that of an Indian woman, aged about 35, who was brought to the hospital with another member of her family suffering from cholera. Before coming to the hospital one of the same family had already succumbed to the disease. On admission it was ascertained that the woman was eight months advanced in pregnancy, and her state of collapse was complicated by total suppression of urine.

Intravenous saline injections, given in the usual way, caused a return of the pulse at the wrist, but with no effect on the secretion of urine. The woman had a show of blood from the vagina, and it was found that the cervix was dilating and that the uterus was endeavouring to expel its contents. Owing to the collapsed state of the patient it was obvious, however, that the power of uterine contraction was inadequate to its task, and knowing from experience the high rate of mortality of pregnant women suffering from cholera it was agreed that the only possible way of saving the woman's life was to empty the uterus. The suppression of urine, if labour had not commenced, would have been a sufficient reason to have emptied the uterus.

When the patient was placed on the table the pulse had again disappeared from the wrist, the extremities were cold and clammy, and she was in extremis.

Intravenous saline injection was again given, and after the saline was seen to be flowing into the vein and the pulse returned,

extraction of the foetus was made as rapidly as possible. Owing to the rigidity of the cervix in cholera cases there is such a great loss of fluid from the body that softening of the cervix, as in normal labour, is absent. Version was performed, a leg brought down, and in this way the os was dilated.

Before delivery of the child my assistant, Dr. K. Gupta, who was giving the intravenous saline, reported that the flow into the veins had ceased; whilst the placenta was being expelled artificial respiration was commenced as the patient had stopped breathing immediately after delivery. The stoppage of the flow of saline into the vein in a cholera case is usually sufficient evidence that the patient is beyond recovery; with the cessation of respiration one can abandon all hope.

However, on this occasion the abdomen was opened and the heart massaged, but with no result. The diaphragm was then opened, and direct massage to the heart undertaken, but again with no result. The heart could now be seen through the incision in the diaphragm and an injection of adrenaline was given. To my surprise the heart began to beat, and what is more wonderful, the blood began to flow into the vein again; in fact, 8 oz. of saline had slowly run in. But during this time, notwithstanding artificial respiration, the woman never showed any signs of breathing, and that she died was no surprise to anyone considering the type of disease from which she was suffering.

This case was as desperate as could possibly be wished to compare the relative efficacy of the two remedies; and although both failed, the chemical stimulant produced some result as against none from the massage.

### ACUTE HAEMORRHAGIC NEPHRITIS FOLLOWING INFLUENZA.

DURING the week commencing November 17th I saw four cases of acute haemorrhagic nephritis: the history in each case revealed that coryza with subsequent cough and bronchitis had preceded the attack.

Cases 1 and 2 occurred on the same day in the same family, in a boy aged 3½ and a girl aged 6. I was sent for on account of the "black water" they were passing. They both looked very ill; the eyelids were puffed, there was pallor of the face, with fever (101° F.) and bronchitis. Both complained of pain in the back and over the lower abdomen, with headache. Both were very restless. Ascites developed in Case 1 (the boy) on the third day.

Case 3.—A boy, aged 12, after a severe influenzal attack for which I had treated him a week previously, suddenly complained of pain over the lower abdomen and back; the water he passed was described by his mother as "like bovril." His symptoms were identical with those of Cases 1 and 2.

Case 4.—A man, aged 53, had coryza for two days, and then came to me complaining of passing scanty, "black" urine. The temperature was 99° F., and the pulse normal, but of high tension.

Examination of the urine in each case revealed the presence of blood in great quantity, the deposit in each consisting of red blood corpuscles and leucocytes, with cell and blood casts. It did not contain pus, but albumin was present in each case in excess. The specific gravity ranged from 1016 to 1025.

Cases 1, 2, and 3 were examined also by Dr. R. A. Askins, Deputy M.O.H. Bristol, who agreed that exanthematous diseases could be excluded.

Southville, Bristol.

ARCHIBALD S. COOK, M.B.

### NASCENT IODINE IN OTORRHOEA.

THE routine treatment of middle-ear suppuration by nascent iodine, as devised and practised by me, has given better results in both acute and chronic cases than any method of equal simplicity at present available. Applicable to every case, it requires no more skill than is involved in the writing of a prescription. Even in acute mastoiditis, where operation, though clinically urgent, was refused by the patient, it has cured apparently desperate cases.

The method consists in the internal administration of potassium iodide with the local application of hydrogen peroxide drops. An adult patient takes 10 grains of potassium iodide, well diluted, every four hours. Every two hours, or even more frequently, the external meatus is filled with hydrogen peroxide, which is retained for ten minutes. The resulting reaction between the absorbed salt and the applied drops liberates nascent iodine within the tissues of the infected middle-ear cleft. With variations of the dosage of the active salt according to age and idiosyncrasy, the treatment is useful in every case of suppurative otitis media.

Ear and Throat Clinic,  
Leigh, Lancashire.

## Reports of Societies.

### GYNAECOLOGICAL TUMOURS.

A MEETING of the North of England Obstetrical and Gynaecological Society was held in Sheffield on November 19th, with the President, Mr. W. Gowan (Leeds), in the chair.

Miss FRANCES IVENS (Liverpool) showed coloured drawings and histological sections to illustrate a case of melanotic sarcoma of the clitoris. The clinical details were as follows:

A married woman, an 8-para, aged about 58, was ten years past the menopause, of healthy appearance, but very stout. She had had an operation for gall stones some years previously, and complained of haemorrhoids. She had noticed a small lump in the anterior portion of the vulva for about twelve months, but it had given her no pain or inconvenience, nor had it discharged. On examination the clitoris was found to be replaced by a softish nodular growth, pigmented in patches, which extended on to the left labium minus. The prepuce of the clitoris was stretched over the tumour. The growth was movable on the deeper structures. Miss Ivens had operated in April, 1925, excising the whole of the vulva as radically and deeply as possible; no enlargement of the inguinal glands was detected. In addition some large haemorrhoids were removed. Primary union occurred, and so far, eighteen months after the operation, no recurrence had followed. The tumour consisted of masses of spindle cells with well stained nuclei arranged in an alveolar manner in a connective tissue stroma. Granules of brownish pigment were scattered through the connective tissue, and were present in some of the cells, but in some areas pigment was absent. The tumour was covered by thinned-out stratified epithelium.

Miss Ivens said that cases of melanotic sarcoma of the clitoris were very rare. In 1908 Eardley Holland had collected three among thirty-two of the vulva. Since then Lockhart had reported one, and mentioned two others. He noted the extreme malignancy of these tumours and their tendency to rapid dissemination. In the present case favourable points affecting the prognosis were the absence of ulceration and fixation, the absence of enlarged inguinal glands, and, probably, the fact that pigment only occurred in patches. As regards the mode of origin of this tumour, it was possible that it arose from the chromatophores or connective tissue pigment cells of the skin; it was therefore a melanotic sarcoma, and not a sarcoma associated with altered blood pigment or sarcoma haemorrhagica.

Dr. J. E. GEMMELL (Liverpool) said he had had a similar case in which recurrence followed within twelve months.

Dr. W. FLETCHER SHAW (Manchester) also had had a case of a large densely pigmented tumour of the vulva, which he had removed very widely with the inguinal glands, and had treated with radium, but recurrence followed in four months, and the patient died in fourteen months.

Dr. LEITH MURRAY (Liverpool) considered that a small amount of pigment did not necessarily mean a low degree of malignancy.

#### Ovarian Cysts and Tumours.

Dr. E. O. CROFT (Leeds) then demonstrated a specimen showing axial rotation of a fimbrial cyst. The symptoms were those of twisting of the pedicle of a cyst with pain on the left side. The ovarian pedicle was not twisted, but the cyst had a corkscrew twist. The other ovary was normal and healthy. Professor M. H. PHILLIPS (Sheffield) and Mr. J. ST. G. WILSON (Liverpool) had both encountered similar cases.

Dr. J. W. BRIDE (Manchester) showed an ovarian cyst in a girl aged 15. He said that the cyst was a dermoid which had excited attention by the development of acute abdominal symptoms due to torsion of its pedicle. Persistent vomiting and acute left-sided abdominal pain had followed a menstrual period about a week previously; and there had been regular menstrual periods since the onset of menstruation, but always with dysmenorrhoea. The patient had a pulse of 130 and temperature 101°<sub>0</sub>, great rigidity in the hypogastrium, and inability to pass water. An indefinite mass was felt in the left iliac region. Dr. Bride had diagnosed ovarian cyst with twisted pedicle, and advised immediate operation. He found the cyst, about the size of a foetal head, with numerous fine adhesions, lying in the utero-vesical pouch, and quite black in colour, and he removed it. The right tube and ovary were normal, and the patient made a good recovery.

Dr. BRIDE also showed a case of fibromata of both ovaries with primary amenorrhoea. He said that this interesting and somewhat unusual specimen had been found by him when investigating a case of primary amenorrhoea in an unmarried girl, aged 19 years, who had consulted him on account of pain in the hypogastrium and feeling a lump there. For her age the patient was distinctly childish; she had never menstruated nor had any moulins. On abdominal examination a hard mass, non-mobile and tender, was felt in the left iliac region, and through the vagina the pelvis was found to be filled with hard nodular growths which he had been unable to separate from the uterus. He had diagnosed ovarian tumour, possibly sarcomatous. On operation he had found the large left and smaller right ovarian tumour, and, being doubtful of their nature and feeling sure that all ovarian tissue was destroyed, he performed panhysterectomy. There was no ascites present, and the patient made a good recovery. Dr. BRIDE added that Hoon had stated that fibromata might occur at any age after puberty; there might be comparatively few symptoms, ascites did not necessarily mean malignancy, and menstruation was usually normal. The tumours in this case were interesting since they caused primary amenorrhoea, and must have been present for some time. This was supported by the evident calcification of the tumours. The childish condition of the patient at 19 years of age suggested complete absence of the ovarian secretion. Dr. BRIDE thought that the statement in textbooks that ascites occurred so frequently in connexion with fibromata as to be almost a symptom ought to be modified. He had seen a certain number of fibromata, and in none had ascites been present. The previous case on which he had operated was in a woman aged 76, and the tumour weighed 4 lb. There was no ascites. Pain as a diagnostic point against fibroids was an important symptom here.

The PRESIDENT did not agree that ascites was so stressed as a symptom.

#### Endometrioma of the Broad Ligament.

Miss IVENS showed also a specimen of an endometrioma which had been removed from between the layers of the right broad ligament.

A girl, aged 20, had suffered from severe dysmenorrhoea with profuse and prolonged menstruation from the onset at 15 years of age. Bilious attacks had been frequent, and two years previously an attack of severe abdominal pain with vomiting had occurred. Dilatation was performed in January, 1925, but the patient became worse rather than better, and in December, 1925, Miss Ivens had opened the abdomen, removed a swollen, kinked, and unhealthy looking appendix, and incised some small cysts of the ovaries. In the right broad ligament, close to but not adherent to the body of the uterus, there was a swelling the size of a large marble, dark in colour, but with no adhesions. It was enucleated, and the peritoneum stitched. On further examination the little tumour proved to be a cyst containing dark tarry fluid. It was lined by cubical epithelium, and showed in its wall typical endometrial stroma and glands embedded in and surrounded by fibrous tissue.

Miss Ivens said that this case was of interest as it supported the view that endometriomata were due to foetal displacement of Mullerian tissue, and not to endometrial grafts. A somewhat similar specimen had been shown by Mr. Beckwith Whitehouse at a meeting of the Obstetrical Section of the Royal Society of Medicine last year.

Dr. K. V. BAILEY (Manchester) suggested that at a later operation endometrioma of the corpus uteri might possibly be found.

The PRESIDENT thought that all the theories had their points, and that epithelial rests explained the process best.

#### Uterine Neoplasms.

Mr. J. ST. G. WILSON described an unusual case of carcinoma of the cervix.

A nullipara, aged 30, married seven years, had complained of intermenstrual bleeding for four months. On examination the cervix was found to be replaced by a crater, which was ulcerating, friable, and bleeding. The supravaginal cervix was thickened and the uterus fixed. There was albumin in the urine. At operation growth was seen on the surface of the uterus. The patient died ten days afterwards. The specimen showed growth infiltrating the whole of the uterus, and secondary growths were found in the lumbar glands. Microscopically the growth was of the squamous-celled variety.

Dr. CROFT commented on the rarity of spread to the corpus.

Dr. FLETCHER SHAW showed a case of acute torsion of a uterus containing a fibromyoma.

The patient was unmarried and 70 years of age. For eighteen months she had complained of recurrent attacks of nausea, which had been attributed to biliousness, but on the last occasion when her doctor had examined the abdomen he had found a large, hard, tender tumour which, the patient stated, had been there for over twenty-five years. A gynaecologist had advised her not to have any operation performed. The tumour was very hard; it extended to the umbilicus, was apparently fixed to the uterus, and was extremely tender. A diagnosis of a degenerating fibroid was made, and an abdominal section performed the next day. It was then found that the uterus contained a fibroid in the fundus about the size of a foetal head and of stony hardness, due to calcareous degeneration. The uterus and appendages were twisted round in two complete turns, and so had formed a narrow pedicle just above the level of the internal os, no thicker than a man's finger. The broad ligaments and tubes were of a deep purple colour, many of the veins were thrombosed, but in some the blood was still fluid, so apparently there was a small circulation still kept up. The tumour was easily removed at the site of the torsion, and the patient made an uninterrupted recovery.

#### ADVANCED ABDOMINAL PREGNANCY.

Professor PHILLIPS described a case of advanced abdominal pregnancy, and said that his object was to draw attention to the frequent difficulty of clinching by the ordinary means of examination this diagnosis. The clinical history might, as in the present case, be highly suggestive, and yet a careful physical examination, by the ordinary methods of palpation and auscultation, might fail to give convincing evidence of the presence of a foetus in the large abdominal tumour. This had been his experience in five out of the six cases with which he had had to deal. On this occasion the clinical story was classically descriptive of this unfortunate form of gestation. Therefore, when he had failed to palpate any part of a foetus in the abdominal tumour, he felt pretty confident that an x-ray examination would reveal one. The photograph showed not only a foetus, but also a position and condition of that foetus which could best be explained by its being dead and in an extrauterine sac. The skull was lying in the left iliac fossa; the bones of its vault were overlapping. The spine lay across the upper region of the abdominal tumour, and was compressed into the arc of a circle in such a degree as was hardly likely to occur within the uterus.

The story was as follows:

A woman, aged 30, had had a dangerous attack of pelvic peritonitis two and a half years previously, after a miscarriage at eleven weeks. This was her first pregnancy. Menstruation was scanty afterwards, but she did not miss a period until March of the present year. Her last period had been on February 13th, and there was a slight show unaccompanied by pain nine weeks after. Morning vomiting, secretion in the breasts, and steady enlargement of the abdomen duly followed. She quickened at four and a half months, and felt movements daily until September 4th, when she had severe abdominal pain accompanied by a dark bloody discharge, and also diarrhoea and vomiting. Premature labour was suspected, and she went into a maternity home. The external os just admitted the finger tip, and in the course of six days the pain and vomiting ceased and the patient was sent home. No further foetal movements were felt, and the breasts and the abdomen lessened in size; a slight, very dark, blood-stained discharge occurred daily.

When Professor Phillips saw the patient on October 21st (thirty-six weeks after the last period) there was a globular elastic mass visibly distending the abdomen and reaching from the pelvic brim to a point two inches above the navel. It possessed none of the signs of an enlarged uterus, and no foetal parts could be made out. On vaginal examination the cervix was soft, the os was closed to the finger, and bimanually the slightly enlarged body of the uterus could be palpated behind and to the right of the lower pole of the abdominal tumour, which could just be reached at the pelvic brim. The pelvo-abdominal tumour felt just like an ordinary cystadenoma of the ovary.

The x-ray examination having established the diagnosis, Professor Phillips opened the abdomen on November 12th, thirty-nine weeks after the last period. On incising the peritoneum about a pint of thin, clear fluid escaped from a localized space within which was exposed a second sac—the amnion—closely shrouding the foetus. This sac contained rather less than half a pint of thick, greenish, opaque fluid. Both fluids were odourless. The foetus was lifted out and the cord divided. The sac was now seen to line the true pelvis and the abdominal cavity to above the umbilicus. The transverse colon, adherent to the abdominal wall, formed the upper limit of the gestation

sac. None of the pelvic organs could be seen through the sac. The stump of the umbilical cord with the contiguous amnion and chorion were separated from the placenta, which was found to be plastered on the upper half of the sacrum and the adjacent lower half of the lumbar spine. In doing this, a certain amount of the placental substance also was torn away, but without causing any bleeding. The placental tissue was of a dull grey colour and appeared bloodless. No attempt was made to separate it from the underlying aorta and other large vessels. The sac having been swabbed dry, the abdomen was completely closed in the usual layers, interrupted sutures being used in each layer.

This operation had been performed only seven days ago. So far the temperature and pulse rate had remained normal as they were before the operation, and there had been no abdominal pain or even discomfort.

#### TREATMENT OF OVARIAN CARCINOMA.

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on November 18th, the President, Dr. ARCHIBALD DONALD, in the chair, Professor BECKWITH WHITEHOUSE showed a woman with ovarian cancer and peritoneal metastases, who had been treated by transfusion of blood and injections of radiated ascitic fluid. The clinical details were as follows:

A woman, aged 48, the mother of five children, had had her right breast removed in October, 1924, for scirrhus carcinoma. She had consulted Professor Whitehouse in March, 1926, for abdominal distension and progressive weakness. Her abdomen was much distended by ascites, and several hard tumours could be felt; a large mass filled the pelvis, extending above the pubis. The abdomen was opened, and it was found that the ovaries had been replaced by masses of growth which had also infiltrated the omentum and studded the visceral and parietal peritoneum with nodules. The greater part of the ovarian masses was removed, but a portion about the size of a billiard ball was allowed to remain on the left side of the pelvis. Ascitic fluid was collected in a sterile vessel and exposed to 100 mg. of radium element in 1,000 c.cm. of the fluid for twenty-four hours. At the end of the operation the patient was transfused with one pint of blood from a healthy young woman who had reached the tenth week of a normal pregnancy. The patient recovered well from the operation, and was subsequently treated by subcutaneous injections of 10 c.cm. of the radiated ascitic fluid twice a week. The dose was reduced to 5 c.cm. seven months later, and had recently been stopped, a total of 500 c.cm. having been injected. Each treatment with ascitic fluid was followed by a marked general reaction. The patient had subsequently done well and there had been no recurrence of the ascites. The masses of growth previously palpable in the abdomen had disappeared, including the deposit in the position of the left ovary; the patient's general condition had improved very markedly.

Professor Whitehouse considered the result very encouraging, though it was too early to form an opinion as to the final state. The treatment had included two different methods of dealing with malignant disease: the first was the introduction into the circulation of a synectolysin by the transfusion of blood from a patient at a period of pregnancy when such a substance, if it existed, was presumably most active. The second method was the employment of the cancer cell vaccine, utilizing the available ascitic suspension, in which the malignant cells had been destroyed by radium and not by heat.

#### Ascites of Unknown Origin during Pregnancy.

Professor HENRY BRIGGS reported the case of a previously healthy woman, aged 40, who had had four children, and had suffered from amenorrhoea for eleven months. The abdomen was increasing in size in consequence of ascites, and marked albuminuria was present. The uterus was enlarged and could be felt as an abdominal tumour; it was removed by laparotomy and the ascitic fluid drained away. No cause of the ascites was found in the peritoneal cavity. The patient made an uninterrupted recovery.

Mr. T. G. STEVENS described the case of a woman who had been under his care during three successive pregnancies in which there was enormous increase in the size of the abdomen due to ascites. On each occasion the patient had a normal full-term delivery, and no cause for the ascites was found at any time. After the first and second pregnancies the ascites rapidly disappeared, but remained for a long time after the third child had been born. The fluid was removed by tapping and no further accumulation occurred.

## TREATMENT OF GANGRENE OF THE EXTREMITIES.

At a meeting of the Section of Surgery of the Royal Society of Medicine held on December 1st, with the President, Mr. V. WARMER Low, in the chair, Professor G. E. GASK opened a discussion on the treatment of gangrene of the extremities.

### *Periarterial Sympathectomy.*

Professor Gask said that his purpose was to restrict the scope of the debate to an exchange of views on the right treatment of an elderly atheromatous patient threatened with gangrene, with special reference to the advisability or otherwise of periarterial sympathectomy. This operation had now been performed often enough to enable some idea of its utility to be formed. The treatment of senile gangrene, either by conservative methods or by amputation, was admittedly unsatisfactory, and it was most desirable, therefore, to know whether this new method was or was not an improvement. The operation first came into prominence from the work of Leriche, who acknowledged that it was suggested to him by Jaboulay, who practised it in 1899 for the treatment of perforating ulcers of the foot. Designed originally to relieve various trophic changes and obscure pains, such as were included under the title of "causalgia"—disorders assigned to disturbances of the vasomotor system—it had more recently been performed for the relief of thrombo-angiitis obliterans, Raynaud's disease, arterio-sclerotic gangrene, and even for ununited fractures, osteomyelitis, and pelvic disturbances in women. After a brief survey of the factors tending to maintain a sufficient blood supply in the limbs, Professor Gask said that the idea of this operation was to divide the efferent sympathetic fibres and thereby abolish the vaso-constrictor control over the whole of that portion of the vessel distal to the point of division. The hypothesis underlying this procedure had, however, been challenged by physiologists, who denied that the sympathetic fibres ran their whole course with the blood vessels, and found that experimental sympathectomy did not increase the temperature or blood flow in the distal part of a limb. It was important, therefore, to consider what happened when this operation was carried out in the human subject, and Professor Gask recounted his own observations in four cases. In one of these (a Jew, aged 34) the operation was completely successful: it was followed directly by a rise of temperature in the affected limb, the blueness of the leg and the pain disappeared, the patient returned to work, and now (two years afterwards) he was still perfectly well. A partial success might be claimed for another case, and in the other two the patients were not improved, though no harm was done. On reviewing the results of this operation as reported in the literature, he could not help being struck by the more or less general agreement with his own results. Sometimes a brilliant success was noted, more often a slight or temporary improvement, and very often none at all. It seemed clear that there was a discrepancy between the findings of the physiologists and the clinicians. Having stated the facts so far as they were known to him, and analysed some of the hypotheses, it seemed that certain conclusions might fairly be drawn. While the results of periarterial sympathectomy were on the whole unsatisfactory, and in senile gangrene good results were not to be expected, it was followed occasionally by an astonishing and unexplained success. In view of the discordant clinical and experimental findings, further knowledge was needed, both about the distribution and function of the sympathetic system and about the more obscure vascular conditions. What, then, was the correct treatment of a patient with actual or impending senile gangrene? Should the leg be amputated, or should an attempt be made to save the limb by rest in bed, warmth, and the application of desiccating powders, aided, perhaps, by sympathectomy? Before looking up the literature he was distinctly in favour of this operation; now he had less belief in it. In conclusion he would say that although amputation might be

called for in senile gangrene as a life-saving measure, yet it was best to stave this off by every means available. Though the work on periarterial sympathectomy might not have helped greatly in the treatment of gangrene, it had not been wasted, since it had broadened knowledge of the sympathetic system and created a bond of interest between physiologist and surgeon—an effect which was bound to be of advantage in the long run.

### *Periarterial Injection of Alcohol.*

Mr. SAMUEL HANDLEY thought that Professor Gask's pessimism about periarterial sympathectomy was not justified by a fair interpretation of his own results. He had shown that in man sympathectomy was followed by an increase in the temperature of the foot, and that fact in itself was sufficient to justify the operation. It was not necessary from a practical point of view to explain these results or to bring them into accord with physiological theories on the subject. Of Professor Gask's four cases one was completely successful, the second a partial success, and in the others at least no harm was done. Sympathectomy gave to these patients an even chance of avoiding amputation. The variable results of periarterial sympathectomy might reasonably be explained as due to anatomical variations in the distribution of the sympathetic nerves, particularly as regards the level at which they joined the artery. It appeared to the speaker that Langley's experiments by no means proved the absence of vaso-constrictor nerves from the outer coat of the arteries, even in the animal experimented upon, and that in any case they could not outweigh the direct clinical observations of the effect of sympathectomy in man. It was a remarkable fact that fundamental observations upon the vaso-constrictor nerves were made by Lister as far back as 1854. Professor Gask would be surprised to hear that he (Mr. Handley) had never done sympathectomy. The method almost universally adopted by neurologists for interrupting the continuity of sensory nerves was to inject alcohol into them, and it appeared to him that this method could be adopted to interrupt the sympathetic nerves upon the outer coat of the artery.<sup>1</sup> His plan had been to inject from two to three minims of alcohol at four points, spaced out around the circumference of the artery and into its outer coat. The artery he had employed had been the femoral in Hunter's canal. Apart from its ease of performance, alcohol injection had advantages over sympathectomy. It was noteworthy that Leriche did not record success in the treatment of actual, but only of threatened, gangrene, so that the alcohol method appeared to succeed in cases not amenable to arterial sympathectomy. He would suggest that in Leriche's operation there were two factors at work: (1) interruption of the vaso-constrictor fibres; (2) a local injury of the muscular coat of the artery causing a local muscular spasm which produced the initial constrictor symptoms. The latter factor was very undesirable, and was easily to be avoided by substituting for sympathectomy the method of alcohol injection. The speaker had performed the operation of periarterial injection eleven times. He gave an account of several of these cases, and recorded three in detail. In the first there was re-establishment of colour in the distal half of the foot which had already become cold and black. The line of demarcation healed up, and fresh lines of demarcation formed round the toes. The toes dropped off, and the patient left hospital three months later with a useful foot, free from pain and able to walk. The second case was one of Raynaud's disease, with gangrene of the tip of the left forefinger. Periarterial injection of the left brachial artery was done, and the patient was discharged twenty-six days later with the finger almost healed and less painful. The third case was one of senile gangrene of the left foot; periarterial injection of the left femoral and Hunter's canal was followed by the arrest of the line of demarcation and complete relief of pain in the limb. The patient, however, died of pleurisy two months after a Syme's operation had been performed. After describing other cases, Mr. Handley said he felt unable to recommend alcoholic injection for any condition other than threatened or actual senile gangrene, although it might possibly be

<sup>1</sup> Sampson Handley, *Lancet*, 1922, ii, p. 173.

of benefit in the gangrene of Raynaud's disease. He had not found in the upper limb such definite effects in raising the temperature of the limb below as were met with in the lower limb. He believed, however, that in senile gangrene, before the word "amputation" was even breathed, a trial should be made of the effects of periarterial alcoholic injection. Even should it fail it might enable a lower amputation to be done than would otherwise be the case. In itself the operation was a safe one, but the danger of absorption of the toxic products of tissue necrosis must be guarded against by doing it early before extensive gangrene had occurred.

Mr. PHILIP TURNER said that although he had never performed the operation of periarterial sympathectomy he had in four cases carried out the periarterial injection of absolute alcohol on the lines recommended by Mr. Handley. The first case was that of a man of 70, with dry gangrene of the right big toe. There had been attacks of pain in both feet for over a year, and since the appearance of the gangrene two months before the pain had been severe enough to prevent sleep. Besides the gangrenous toe there were large discoloured patches on the dorsum of the foot, and the whole foot was swollen and was colder to the touch than the sound foot. The femoral artery when exposed in Hunter's canal was found to be a rigid calcified tube; no pulsation could be detected. The delicate outer coat was injected with 10 minims of absolute alcohol, introduced through four punctures with a very fine hypodermic needle. This produced a grey discoloured area, about half an inch long, round the whole circumference of the artery. Next day the pain had disappeared, two days later the swelling of the foot had gone, a few days later still the areas of apparent gangrene on the dorsum and sole of the foot recovered; in a fortnight the formation of the line of demarcation had rapidly advanced, and in a month the toe had separated after the tendons had been divided with scissors. The patient then started to walk about in comfort, but it was many months before the granulating surface left by the separation of the toe had healed. He continued to do well, and a year after the operation had moved away into the country. The patient's doctor now stated that the wound remained healed two and a half years after the operation; there was no recurrence of gangrene, the patient was well, without pain, and able to get about. Mr. Turner also described his other cases, one of which promised to be a success until cerebral haemorrhage occurred, and the other two were failures; but in both the patients' condition was so unsatisfactory that they would probably have died in any case. In three of the cases, and to some extent in the fourth, the operation was followed by increased warmth of the foot, which could only have been due to an increased amount of blood in the tissues. The technique was not quite as easy as it appeared at first sight. A very fine needle was essential. One advantage of the operation was that it offered an alternative to amputation. He was decidedly in favour of it, and believed it would help, in Professor Gask's words, "to stave off amputation by every means in our power."

Mr. J. P. ROSS said that Professor Gask had laid stress on the discrepancy between the facts bearing on the sympathetic supply to the blood vessels as discovered by physiologists, and the clinical results of periarterial sympathectomy. A possible explanation of this discrepancy was that in the operation it might not be the efferent nerves to the vessels that were removed, but afferent nerves from the blood vessels to the spinal cord. The muscle of the arteries, especially the arterioles, and the contractile tissue of the capillaries possessed tonus which was controlled by vaso-constrictor and vaso-dilator nerves. Sherrington had likened the control of this tonus to the control of the tone of voluntary muscle, which was regulated partly by a reflex arc—an afferent neurone from the muscle, a synapse in the cord, and an efferent neurone back to the muscle. There might possibly be a similar arc to control blood-vessel tonus. There was plenty of evidence—histological, experimental, and clinical—that afferent fibres did pass from the blood vessels to the central nervous system, and mostly from the proximal portions of the limb vessels. It was conceivable that the arc controlling tonus was broken

on the afferent side by the operation of periarterial sympathectomy, and this would explain why an operation on the proximal part of a limb could affect the distal portion. Two points—one of experimental and the other of clinical interest—might be mentioned in this connexion. Section of the depressor nerve, the great afferent nerve from the aorta, led to vaso-dilatation all over the body. It therefore seemed possible that division of afferent fibres on the femoral artery should lead to vaso-dilatation in the leg. The clinical observation that the operation was immediately followed in all cases by relief of pain suggested strongly that afferent impulses were being blocked on their way to the central nervous system.

Mr. E. G. SLESINGER had performed periarterial sympathectomy fourteen times on eight patients. He could see no advantage in Mr. Handley's alcohol method over the operation of stripping, and thought the danger of injecting alcohol so close to the muscular coat to be just as potent as that of surgical section. The primary vaso-constriction seemed to be due to trauma of the muscle coat and could be avoided by gentle handling. It was most important to verify the tissue removed as being nerve plexus by section; in some cases of failure areolar tissue only might have been removed. Of his cases two were Raynaud's disease affecting the anus, and in both the pain and tingling which had prevented sleep disappeared and the colour improved. Two were cases of thrombo-arteritis obliterans with gangrene, and the pain disappeared. In one case of senile gangrene affecting the heel complete relief followed, and in one of arterio-sclerotic gangrene, with one leg previously amputated, there was marked improvement. The remaining two cases were of obscure pathology. One was a man with calcification of the arteries who had recurrent attacks of phlebitis, with gangrene of two toes and of the other heel. He showed a curious change after the operation, developing what the speaker thought was an acute eczema of one foot and leg. Dr. Semon, who saw the case, considered it to be an exudative condition with no sign of inflammation. The last case, a recent one, was a patient from East Africa who had a chronic ulcer on one heel and gangrene of the opposite big toe. At operation the artery on both sides presented an acutely oedematous condition of the adventitia, with acute injection of its vessels. Periarterial sympathectomy was done, with relief of pain. The ulcer on the heel had healed, and the toe appeared to be doing so, although only six weeks had elapsed. Mr. Slesinger emphasized the lack of knowledge of the state of the vessels in these gangrene cases in the living, and thought that this operation would throw light on that subject. In his view the relief of pain justified the procedure. He had always proposed it as a pure experiment, without promising results, and in all his cases the patient had asked for it to be done on the second limb when two limbs were affected.

## ZOOLOGICAL NOMENCLATURE IN MEDICAL LITERATURE.

At a meeting of the Section of Tropical Diseases and Parasitology of the Royal Society of Medicine, held at the society's house, 1, Wimpole Street, on Wednesday, December 1st, at 5.30 p.m., the President, Professor R. T. LEIPER, F.R.S., read a paper on the tyranny of nomenclatural rules in medicine.

Before commencing his paper Professor Leiper stated that he regarded it as a high privilege to follow Sir William Prout and Sir Leonard Rogers as president of the section. With them he was one of the small band of workers who initiated the section, believing that tropical medicine should be given a recognized place among the other branches of the Royal Society of Medicine. The work of the section was in no way antagonistic to the Royal Society of Tropical Medicine, to which every medical man working in the tropics should belong. There was a wide field for both bodies, and support was obtained for that view by the preparations now being made by the British Medical Association to form a Tropical Diseases Section for its Annual Meeting at Edinburgh next year:

members of both societies were being asked to share in the organization of this section.

The announcement, continued Professor Leiper, that a new International Congress of Zoologists would meet next summer made pertinent the subject of the tyranny of nomenclatural rules in medicine. The parasitologist suffered more than most zoologists from changes in the names of the subjects in his own group, and was compelled to keep abreast also in names of an immense number of vectors and hosts.

At first sight the operation of the laws of nomenclature appeared to offer a prospect of stability and nomenclatural tranquillity, but it was discouraging to find that after two decades there was neither certainty nor peace. During his own time Dr. Leiper had seen many changes in the scientific names of the common helminths of man. These alterations had been a source of considerable annoyance to medical men and bitter complaint from medical students; this had been attributed to ignorance of universally applying rules. Everyone, however, was now aware of their existence, and this could hardly be the cause. He did not believe, however, that it could seriously be maintained that the rules were applied as rigidly and consistently to early as to more recent records. The "law of priority" insisted on the employment of the earliest record, provided it was published and accompanied by some definite indication and that the author applied the principle of binary nomenclature. Works previous to 1758 (when Linné published the tenth edition of his *Systema Naturae*) were not regarded as binominal. But many of the workers subsequent to Linné did not consciously put the binary system into practice. Goetze, for example, in 1782, did not accurately follow the Linnaean method; yet the names of several important parasites had been changed during recent years to give priority to his names—for example, *Taenia mediocanellata* has been replaced by *Taenia saginata*. Similarly *Diectophyme* was generally replacing *Eustongylus*, although the name had been used as a colloquialism by its French originator. *Dracunculus* was merely a vernacular term for the guinea-worm until used by Cobbold in 1864, by which time it had been applied to a group of reptiles many years previously. One of the rules of nomenclature required the citation of the author's name immediately after the specific name in order to hold him responsible and as a bibliographical aid. But this rule was loosely applied to the earlier works—for example, *but* was not originated by Guyot as was usually stated; he merely quoted the word as the native vernacular name for the eye-worm, and it was not made a specific name until 1864, when Cobbold used it as such.

Recently the well known *Filaria bancrofti* had been placed in the genus *Wuchereria*, which was attributed to Araujo. On a recent visit to America he had discovered that *Wuchereria* was used by Araujo as a specific, not generic, name, and used, too, before *bancrofti*. The name was used in 1921 by Seurat in a generic sense, and the modern name should be therefore *Wuchereria wuchereria* (Araujo, 1877), Seurat, 1921. But this also was probably incorrect, as under the rules compound words might form a valid specific name if used to connote a simple object, and this parasite had been called *Filaria sanguinis hominis* at an earlier date than *Wuchereria*. *Filaria sanguinis hominis* was not trinominal; it represented a simple object—namely, the blood of man—and seemed as valid as those quoted by the Commission as acceptable. This parasite might ultimately have to be called *Wuchereria sanguinis-hominis*.

This state of affairs appeared intolerable. The International Commission, however, had plenary power to suspend any of the rules which seemed to cause greater confusion than conformity. Steps should be taken to press for an extension of this ruling to place well established names upon a list. The principles guiding the compilation of this list should be (1) the use of the name in most common use, (2) a name if possible describing the disease, (3) a name conforming to the vernacular or technical foreign names, (4) the law of priority should not be applied. Such a list, keeping as much as possible to traditional names, would lighten the task of the teacher,

and of the student, who often wasted valuable time in committing to memory lists of names unfamiliar to him but describing familiar parasites. The alternative was to depart entirely from zoological nomenclature and adopt an agreed scheme of medical terminology which was subject to no rules of priority.

He suggested that some independent body might be willing, after consultation with teachers, writers, and investigators, to undertake the preparation of a nomenclature for medical parasitology.

Dr. MASSON-BAHR said that he agreed with Professor Leiper in principle, but in the past he had followed the teaching of authorities in the matter of nomenclature. He suggested that names might be standardized as they were at present. Dr. NICOLA agreed that the time had come when some steps must be taken to stabilize medical nomenclature. The International Commission had done much to improve matters, but the constant endeavours of some parasitologists to search old records in an attempt to stabilize matters had caused much confusion. He believed that some plan might be discovered whereby everybody—medical and zoological—might have some common stable scientific nomenclature. Sir LEONARD ROGERS considered that there were too many systems of classification and nomenclature, and suggested that the ordinary terms in textbooks might form the basis of a permanent system.

#### Papers.

Papers were contributed by Dr. S. V. VAN NIEKERK of Natal on two cases of pseudo-hermaphroditism in native labourers in Johannesburg; by Dr. AZIM on a species of *Eimeria* in rats in England; and by Miss HILES on various methods of diagnosing hydatid infections in man, including the complement fixation test, the precipitin test, and the Casoni intradermal test.

#### JAMES MACKENZIE INSTITUTE.

##### Arterio-sclerosis.

PROFESSOR ASHLEY MACKINTOSH, on November 9th, reviewed first the groups of causes known to influence or to co-operate in the production of arterio-sclerosis, and emphasized the importance of first removing these in any attempt at treatment of the condition. He mentioned amongst these "wear and tear," especially from worry, and infective or toxic causes, not necessarily of gastrointestinal origin. In this connexion he professed himself a believer in an hereditary variation in the viability of the vessels. The lecturer was emphatic in his belief that the most effectual régime for the sufferer from hypertension was one in which avoidance of any thoughts centred on himself was ensured, as far as possible, and for this reason he deprecated the too frequent recording of blood pressure readings, and insisted on the avoidance of a "hypertension hypochondriasis" (Osler and McCrae). He found greatest benefit from a mode of life which involved as little interference with habits, work, and food as possible, especially in elderly patients, and outlined in detail the ideal diet for the hypertension subject. In this he did not reduce protein drastically, but allowed 3 to 5 oz., especially of white meat, per diem, believing that too much importance had been ascribed to protein overfeeding. Diets must not be cut down so far as to lower the patient's general condition. He outlined the proper care of the skin and bowels, and strongly advocated the weekly or bi-weekly use of calomel. Under medicinal treatment he described those drugs from which he had had beneficial results, but before doing so put the question as to how far hypertension was a compensatory function, and he showed that it was not apparently so in so far as the kidney was concerned, there being no proved relationship between the power of concentrating urea and the blood pressure. He referred to other methods of treatment, such as sympathectomy, by electrical methods, and

Finally, he urged the importance of watching the heart carefully in every case of arterio-sclerosis, and sketched the methods which were of service in the treatment of acute complications, such as anginal attacks or oedema of the lungs.

## Rebuelus.

### DERMATOLOGY.

SOME years ago an American dermatologist, writing in one of the journals devoted to his specialty, expressed his opinion that there were too many textbooks on general dermatology and too few monographs on particular branches of the subject. While this may be true so far as the specialist is concerned, it does not apply to the profession as a whole; indeed, it is only through the agency of the standard works that the practitioner can hope to learn the trend of modern dermatology, and it is significant that Dr. J. H. SEQUEIRA points out in the preface to the fourth edition of his well known *Diseases of the Skin*<sup>1</sup> that its appearance has been unavoidably delayed by, among other things, the enormous output of dermatological literature since the war.

The task of selecting from this mass production of post-war literature what seems of importance, or appears likely to be of permanent value, has been carried out by the author with careful discrimination, and the short bibliographies appended to the sections will be found particularly useful by those who desire to consult the original papers. Throughout the text the reader cannot fail to perceive the impress of the author's great personal experience. We think Dr. Sequeira has been wise to resist the temptation to expand and enlarge the book, which, although it contains much new material, remains of exactly the same size as the previous edition. The same high level of excellence is reached, and we are confident that the book in its new dress will achieve the success its many admirable qualities deserve.

### THEORIES ABOUT CANCER.

ALL questions relating to the causation of cancer are at present so dominated by the recent discoveries of Gye and Barnard that the older theories have to a considerable extent lost colour. Nevertheless, in so far as the latter provide an impetus to the discovery of new facts and suggest lines of investigation, their value is not to be overlooked. A case in point is the volume recently published by Professor van Calcar of Leyden on the cause of cancer.<sup>2</sup> He is convinced of the protozoal origin of cancer, and he has recorded some interesting experiments in support of the theory. Thus, inflammatory foci are found in the livers of dogs and some other animals, which contain a small trematode, the *Metorchis truncatus*; if these worms are placed in a decoction of wheat and studied under the microscope, they will be found to disintegrate in the course of a few days, and in some of the cultures minute flagellate protozoa will develop. Van Calcar found that the protozoa only developed from trematodes which were taken from foci exhibiting atypical epithelial proliferation and not merely simple inflammatory changes. In the case of experimental tar-cancer, again, the author considers that protozoa are derived from the food and the surroundings of the animals, in which they may occur in enormous numbers. If cancer is related to the presence of protozoa the number of positive results should diminish when precautions are taken to protect the animals from contact with protozoa. This was found to be the case; in the great majority none but simple inflammatory changes occurred. Other experiments were suggested by Stahl's experimental production of cancer of the tongue in rats by feeding them on oats, the roughness of the grain causing abrasions of the mucous membrane. Van Calcar has found that smooth grain, such as wheat, will produce the same result, provided an artificial abrasion is made; and he has also shown that protozoa can be cultured from these and other types of grain in abundance. In two experiments he inserted, beneath the intestinal mucosa of dogs, grains of oats and wheat in which protozoa were known to be present; in both he obtained positive results. In another series of experiments he curetted away a small area of the gastric

mucous membrane, and fed the animals on food containing protozoa derived from various sources—from grain, from cockroaches, from larvae developed in decoctions of grain, and from foci of metorchis in the liver. In all cases he obtained malignant growths showing atypical proliferation, anaplasia, numerous mitoses, infiltration, and metastases. The instances cited all presuppose a local precancerous condition of some kind. As an example of a generalized precancerous condition the author takes achylia; a dog in which the stomach had been excised two years previously was given water containing protozoa. It became emaciated and died in a few weeks. Numerous small tumours were found in the mucous membrane of the stomach and intestines with metastases in several of the mesenteric glands. Van Calcar discusses fully the histology of these induced carcinomas, and illustrates what he has to say by a large number of microphotographs. His experiments on the culture of protozoa from carcinoma are, perhaps, less impressive. The method adopted was to make an emulsion of tumour substance in sterilized water, distribute the liquid over a number of Petri dishes, remove the cover of the first culture after twenty-four hours, of the second after forty-eight hours, and so on till all the cultures had become dry. The dried mass was then moistened and, as far as possible, distributed through water. In some cases rapid drying by means of a powerful desiccating agent was employed. In the cultures so obtained, both from experimental tumours and from those removed surgically, the author repeatedly met with structures which he considered to be morphologically identical with the spores of protozoa.

Dr. OTTO WARBURG has collected a series of articles on the metabolism of tumours<sup>3</sup> that have appeared in various periodicals during the last eighteen years, and has added some chapters on experimental technique. The volume embraces an important series of observations on the characteristics of cancer metabolism. Having observed that the oxygen metabolism of the ovum of the sea-urchin increased sixfold on changing, under the influence of fertilization, from the resting to the active condition, Warburg conceived that the abnormal activity of the cancer cell might be due to a similar high oxygen metabolism. This proved not to be the case, the cancer cell showing no difference from the normal resting epithelium in this respect. He then suspected that the source of the enhanced energy of the cancer cell would be found in ferment metabolism (glycolysis, or the conversion of sugar into lactic acid). That the cell does actually utilize this source of energy he proved in the following way: A slice of rat carcinoma was placed for twenty-four hours in warm Ringer's solution, saturated with nitrogen to ensure anaerobic conditions and the exclusion of oxygen metabolism. It was found that if the solution contained sugar the tumour could be transplanted as readily as in the fresh condition; but if it contained none the tumour ceased to be transplantable. Ferment action alone, and in the absence of oxygen metabolism, was thus shown to maintain the vitality of the cell. A series of experiments was next planned to show what modification in the anaerobic glycolysis resulted from an access of oxygen. It had already been shown that, in the case of muscle, an access of oxygen will prevent the appearance of lactic acid—that is to say, the glycolysis disappears. In cases, however, where anaerobic glycolysis is large in amount, as in yeast fermentation, and oxidation metabolism is relatively weak, glycolysis persists even in aerobic conditions. Such was found to be the case with the cancer cell. In this respect it differs from the cells of non-malignant tumours; in the latter, anaerobic glycolysis is similar to that in cancer, but oxidation metabolism is much greater, non-malignant tumours producing three to four times less lactic acid per molecule of oxygen absorbed than cancer. It is to be noted that the difference is one of degree rather than of principle. On comparing embryonic tissue with pathological growths, Warburg found that anaerobic glycolysis was similar—that is, it was large in both—but that in embryonic tissue, in contrast with cancer, the metabolism in the presence of

<sup>1</sup> *Diseases of the Skin*, By James H. Sequeira, M.D., F.R.C.P. Lond., F.R.C.S. Eng. Fourth edition. London: J. and A. Churchill, 1927. (N.S.) 8vo, pp. xii + 644; 399 figures, 56 plates. £2 2s. net.)  
<sup>2</sup> *Die Ursache des Carcinoms*, By Professor R. P. van Calcar, Leyden: S. C. van Doesburgh, 1925. (Roy. 8vo, pp. 66; 45 figures. Fl. 3.60.)

<sup>3</sup> *Über den Stoffwechsel der Tumoren*, Herausgegeben von Otto Warburg, Berlin: J. Springer, 1926. (Roy. 8vo, pp. 263; 42 figures. R.M. 16.50; bound, R.M. 18.30.)

oxygen is a pure oxidation metabolism, glycolysis disappearing under aerobic conditions. This he regards as the main point of difference between normal and pathological growth. It might be supposed that if the oxygen metabolism of an embryonic cell were reduced from any cause the cell would acquire the characters of a cancer cell. This, he thinks, does not happen, because embryonic cells cannot survive under anaerobic conditions, whereas the cancer cell can, as was pointed out above. With regard to adult resting tissues, these are in reality slowly growing tissues and therefore exhibit a slight glycolysis. The relation of cancer metabolism to that of other cells may, according to Warburg, be thus stated: In embryonic cells there is a large anaerobic glycolysis with a correspondingly large oxidation metabolism; in adult stationary tissue there is a small anaerobic glycolysis with a relatively large oxidation metabolism; in carcinoma arising from the stationary condition of the cells the glycolysis is again increased to the embryonic amount, but no corresponding increase in the oxidation metabolism occurs. The experimental data on which these conclusions are based are fully stated in Warburg's book.

Although lucidity is undoubtedly the primary desideratum in scientific writing, there is no doubt that an author adds charm to his literary work by leaving somewhat to the reader's imagination. This, however, can be carried too far, and we think that Dr. Greil's book on the cancer problem is open to criticism in this respect. Voltaire's dictum that language was given to us to conceal our thoughts should not be followed to the point of complete incomprehensibility. Dr. Greil has to some extent compensated for this defect by inserting several critical reviews of his work by writers who are endowed with the faculty of interpretation, and from these it is possible to gather a general idea of his meaning. Thus Dr. Dürck writes as follows:

"Dr. Greil's treatise, which he designates a 'programmatical exposition,' explains tumour formation as a disordered process of early embryonic development. It must be admitted that his manner of rendering his ideas acceptable is complicated in the extreme, not to say eccentric. The language he employs requires a study in itself, and is permeated with conundrums and words of his own coinage. He explains that all growth forms arise from cell-municipal potential acquisitions between daughter cells and neighbour cells, layers and tissues, at the wrong place and wrong time, and in wrong intensity and wrong combination. Among these cell-municipal potential acquisitions are included, the acquisition of layer differentiation, layer support by favourable metabolic conditions, marginal or apical differentiation through tensional release, altior potential of palisade tracts, haemo-vasogenic potential through unequal space differentiation of vascular channels, intercalation in the transit and discharge of reaction products of neighbouring layers with higher potential, distraction potential with demarcation of growth foci, and so on. It is usual to associate language with thought, but with the best will in the world mental processes are nonplussed amid the whirligig of the author's sentences. At every page we are confronted with monstrosities of word and phrase, confounding the understanding. We regret, therefore, that we are unable to express an opinion with regard to the meaning of many of the author's chaotic utterances. If we understand him aright, he considers one of the causes of tumour formation to be the close connexion of the foetus with the mother, the foetus forming a segment of the materno-foetal total constitution; and that abnormal changes in the maternal metabolism react on both organisms. Among these changes Greil reckons a disposition to tumour formation—a neoplastic diathesis—but how this comes about is by no means clear."

We do not recommend this book to those who have not a fair knowledge of the German language; a dictionary is of little assistance.

#### THE CEREBRO-SPINAL FLUID.

The Association for Research in Nervous and Mental Disease makes its contributions to medical literature in the grand style. This society of American clinicians and experimentalists meets annually to deliberate upon some special problem within its field of interest. The complete proceedings are then handed on, without any undue haste, to a larger audience in the form of a large and elegant volume, of which the most recent is the *Human Cerebrospinal Fluid*,<sup>2</sup> being the report of the conference

held at the end of the year 1924. The symposium takes the customary form of a series of papers introductory to general discussions of the subject from various angles. The latter are preserved in the form of question, answer, and spontaneous comment, though competent editing has served to eliminate the equivocations which arise inevitably in unrehearsed discussion. This form certainly enhances the interest and mitigates the severity of the objective contributions with a human note and the sense of the impact of personal opinion and experience.

It is claimed for the book that it is the most comprehensive survey of the physiology and pathology of the cerebro-spinal fluid which we have. The claim must be conceded. Introductory papers deal with the history of the fluid, a résumé of the literature, and a comprehensive analysis of the biological, chemical, and physical characteristics of the fluid in normal and abnormal conditions. Those who find occasion to employ the colloid tests generally advocated will be interested in the record of the comparison in 400 cases of the gum benzoin, colloidal gold, and mastic tests. Full protocols are given, and it is to be observed that discrepancies were encountered in only 16 cases.

Some interesting pressure studies are reported which include observations upon the effect on hypertension of the injection of a variety of hypotonic solutions. A plea is entered for the synchronous determination of pressure at different places in the diagnosis of brain and cord tumours. The value of and risk attending the employment of lipiodol and the method of simultaneous displacement of fluid by air as aids to ventriculography are discussed from the experience of several members. There follows an extensive survey of the changes which are found in the cerebro-spinal fluid in all types of diseases of the central nervous system and in certain extraneural conditions; the concluding section deals with intraspinal treatment, particularly in respect of syphilis of the central nervous system. Over 5,000 recorded examinations form the basis of the clinical contributions, which cover nearly every conceivable pathological state.

It is but two centuries since the ridicule of Goethe sought out those who found in the fluid of the cavities of the brain the vehicle of the animal spirits—the very organ of the soul. It is but thirty-five years since Quincke set the fashion for lumbar puncture, which has to-day become routine for diagnostic and therapeutic purposes. For the interpretation of the chemical, physical, and bacteriological assay of the cerebro-spinal fluid and of x-ray and pressure observations, this elaborate—but, alas! costly—volume should become the standard work of reference.

#### THERAPY EXPERIMENTAL AND PRACTICAL.

The publication has begun of a book on practical therapy<sup>3</sup> based on experimental investigation, edited by Professor von DEN VELDEN and Dr. P. WOLFF. It is one of the big co-operative works which are so much in favour with German publishers just now. The first volume, which is in two parts, contains over 1,100 pages, and deals with the general principles of therapeutics. In the second, the therapeutic measures appropriate to the various diseases are to be considered.

In the preface the editors discuss the present position of therapeutics. They point out that no rational therapy was possible until physiology and pharmacology had developed sufficiently to provide a basis of exact knowledge, and that in consequence the founders of modern medicine in the middle of last century gave attention chiefly to the diagnosis of disease based on the exact science of morbid anatomy. Virchow expressed the general attitude to therapeutics of the leaders of medical thought in all countries when he said: "Therapeutics must free itself from empiricism, and by the help of pathological physiology rise to be a science, which to-day it is not." Unfortunately this development has been very slow in coming. Virchow's school, which had many influential adherents among English teachers, performed a great service in

<sup>1</sup> *Das Krebsproblem*. Von Dr. Alfred Greil (Innsbruck). Leipzig: J. A. Barth, 1925. (Med. 8vo, pp. viii + 382. R.M. 6.)

<sup>2</sup> *The Human Cerebrospinal Fluid*. An Investigation of the Most Recent Advances as reported by the Association for Research in Nervous and Mental Disease. New York: R. B. Hoeber, Inc. 1926. (Med. 8vo, pp. xxvi + 568; 68 figures. 10 dollars.)

<sup>3</sup> *Handbuch der Praktischen Therapie*. Edited by Prof. Dr. P. Wolff and Dr. R. von den Velden. Erster Band. Leipzig: J. A. Barth, 1926. (Sup. 105. 8vo; Part I, pp. viii + 534, 4 figures; Part II, pp. 593, 11 figures, 2 plates. R.M. 66; bound, R.M. 73.50 the two parts.)

medicine by their nihilistic attitude, which resulted in clearing away a mass of irrational empiricism, but unfortunately nothing was put in its place, and new devils entered into the chambers which were swept but not garnished. The editors of the volume under review believe that the modern developments of physiology and pharmacology are now adequate to provide a scientific basis for a large part of the art of therapeutics; their object has been to collect this information, and to this end they have enlisted some fifty contributors, including many of the best known leaders of the medical sciences in Germany.

The first few articles of the first part of the first volume are introductory and historical; one of the most interesting of them is by the veteran Professor H. H. Meyer, who writes on the importance of experiments to clinical therapeutics. He has watched the birth of pharmacology as a separate experimental science, and has himself played an important part in its development. He emphasizes the fact that although animal experiments are essential yet they remain incomplete unless linked up with clinical observations, and reminds the younger school of pharmacologists of the debt that science owes to the founders of pathological physiology, most of whom were clinicians.

Other interesting and even amusing articles are on senseless and harmful therapeutics, by Professor von den Velden, and on pharmacological impossibilities in therapeutics, by Dr. Oppenheimer. Both are written from the practical standpoint, and contain numerous examples from actual medical practice. Subjects on the border-line of pathology and pharmacology are dealt with in a series of articles. One by the late Professor Wassermann deals with the fundamentals of serotherapy and immunotherapy; in other articles are described the general principles of non-specific protein therapy, anaphylaxis, climatotherapy, balneotherapy, radiotherapy, electrotherapy, and the influence of exercise and diet on health. This list of subjects will serve to indicate the very wide field covered by the volume.

The second part of this first volume deals with the pathophysiology and therapy of each system in turn; lastly come a few articles on the relation of therapeutics to forensic and preventive medicine.

The general ideas which led to the compilation of this volume are excellent, for the amount of information collected is the best proof that a sufficient amount of accurate knowledge of the physiology of the body in health and disease exists to permit at least the foundations of a science of therapeutics to be laid, even though in many cases this knowledge is still insufficient, and only an empirical basis is as yet possible. This first volume is a well planned attempt to collect the data available to form a basis for rational therapy; it deserves careful study by all who are interested in the advance of therapeutics.

#### LATENT PULMONARY TUBERCULOSIS.

THE tuberculous lesions covered by the title of the book on latent pulmonary tuberculosis,<sup>7</sup> by J. RIEUX, include all those of the ganglio-pleuro-pulmonary system that cannot be shown by our present clinical methods nor by the discovery of tubercle bacilli in the sputum to be in a state of evolution. This definition necessarily includes abortive, quiescent, and regressive tuberculosis. The author is, however, interested not so much in following the retrogressive phases of a lesion that has once been open as in deciding on the activity or non-activity of a lesion that has never been clinically manifest. It is with the object of helping the practitioner to form an opinion on this point that the book has been written. We may say at once that the author has nothing new to contribute to the technique of examination; no infallible laboratory test to relieve the clinician of the responsibility of personal diagnosis; no wide generalizations by which every observation may be interpreted; his method is rather to inquire into the various means of diagnosis that are at present available, and to assign to each a particular value. With thirty-five years of experience in the French army behind him he is well qualified to do this.

<sup>7</sup> *La Tuberculose Pulmonaire Latente*. Par J. Rieux. Paris: G. Doin. 1925. (Med. 8vo, pp. xvii + 247; 12 plates. Fr. 36.40.)

His main thesis is that, with care, it is possible in a large proportion of cases to arrive at a diagnosis of latent tuberculosis. The means he employs are three: (1) clinical, in which particular attention is paid to the patient's past history and to the physical examination; (2) radiographical, especially photographs taken with a stereoscopic camera; and (3) biological, among which the cuti-reaction and the complement-fixation test figure most prominently; the former he prefers for children, the latter for adults. It is interesting to note the respect that the author entertains for the complement-fixation test. Unfortunately the weight he places on it is out of proportion to the evidence he can bring to support it. His argument appears to be this: because 85 per cent. of patients with open pulmonary tuberculosis give a positive reaction, and because there is good reason for regarding it as specific, is it not probable that any person suspected of tuberculosis who reacts positively to the test is actually suffering from the disease? This may appear to be a sound argument, but as yet it is nothing more. From experience, however, the author has come to regard a positive reaction in a suspected patient as extremely suggestive of active tuberculosis; a negative reaction, of course, is of much less importance. If he could only prove his case he would render the diagnosis of latent tuberculosis very much more simple.

#### NOTES ON BOOKS.

ONE of the "Psyche Miniatures" published in connexion with the quarterly journal of that name is on the subject of *Over-Population*.<sup>8</sup> Its author, Mr. P. SARGANT FLORENCE, is lecturer in economics at Magdalene College, Cambridge. It constitutes an inquiry into how far recent statistical and theoretic contributions fit into the Malthusian argument that population is necessarily limited by the means of subsistence, and is regulated by preventive measures of checks on birth rate and by the positive checks of misery and vice in increasing the death rate. The tendency of population is to respond to and outrun any increase in the means of subsistence, and this tendency is manifest in existing unemployment. The author favours the Malthusian theories of this tendency to over-population, and points out that Malthus's aim was to urge people to avoid the positive check on over-population, that led through misery to death, by using moral restraint, which was in his day the leading method of preventing births. Recent views of statisticians, such as those of Mr. Yule in his presidential address to the Royal Statistical Society in 1924, attacked the supposed correlation of birth rates with the use of preventive checks, and substituted variations in fertility as the important factor in limiting increase in population. Mr. Sargent Florence does not agree with this, and brings forward considerable evidence to illustrate his point that the great decline in birth rates of European countries is synchronous with the knowledge of contraceptives and birth control. He favours the view of those who urge a limitation of the families of the poor parallel to the existing limitation among the rich, and believes that the future curve of population will be affected by influencing the poor, just as the propaganda of Bradlaugh and Mrs. Besant affected the curve in the past by its influence on the middle classes.

Dr. CHANDLER wrote his little book on *Animal Parasites and Human Disease*,<sup>9</sup> not primarily as a textbook for the parasitologist, but as a readable volume which could be understood and appreciated by all interested in the progress of science and civilization. That he has been successful in his aim is shown by the fact that a third edition has been found necessary within eight years of the publication of the first. In style and substance it has changed little. The chapter on kala-azar has been revised, while the therapeutical portions of those dealing with sleeping sickness and dysentery have been modernized. Recent work on the treatment of hookworm disease and on the biology of the flukes has been incorporated. Otherwise the third edition is unchanged save for minor corrections; there are still a number of these to be made, however, and the references should be brought up to date. Nevertheless, the volume remains a useful survey of human parasitology, and no better elementary textbook can be recommended.

<sup>8</sup> *Over-Population: Theory and Statistics*. By P. Sargent Florence. Psyche Miniatures: General Series. London: Kegan Paul, Trench, Trubner and Co., Ltd. 1926. (4 x 6½, pp. 66; 1 figure. 2s. 6d. net.)

<sup>9</sup> *Animal Parasites and Human Disease*. By Asa C. Chandler, M.S., Ph.D. Third edition revised. New York: J. Wiley and Sons, Inc.; London: Chapman and Hall. 1926. (Med. 8vo, pp. xiii + 573; 254 figures. 22s. 6d. net.)

It is not easy to surmise what object Sir Bampfylde Fuller had in view when he wrote his book *The Law Within*.<sup>10</sup> In his introduction he says that during the last fifteen years his thoughts have been occupied with endeavours to discover the laws which underlie human nature, "to bring within the domain of scientific generalization man's various activities—whether in industry, politics or war, in self-centred, social or religious life, in science or in art." The author confesses that although he has written several books on the subject they have received scant attention, and perhaps we may help with the suggestion that his purpose lacks clearness, that his method is discursive, and his length inordinate. Apparently, having found no satisfaction in biology, physiology, and psychology; Sir Bampfylde feels the need of a new science, to which he gives the name "biothymology." Psychology, he thinks, has failed because it has practically ignored the law of evolution; while biology and physiology have closed their eyes—strange to say—"to the quality which must exist in the constitution of all living organisms—whether animals or plants—that are formed by the combination of two sexual elements." Biologists, influenced by the utilitarian spirit of the age, have clung to the belief that changes which have come about through evolution have always been purposeful; whereas, according to Sir Bampfylde, evolution may be expressive as well as useful, and Nature may be as magnificently purposeless as Art. In developing the thesis—whatever it may be—a vast amount of ground is covered. We learn that feminine energy is inclinational, and therefore practical and purposeful; while masculine energy is expressive and emotional. We are given as the argument against socialism the statement that idealism, being a motive of expression, "cannot maintain its ardour against the chilling effect of practical considerations." We are told that admiration is not as powerful as apprehension in withstanding onsets of cupidity or anger; consequently that the League of Nations will hardly hold its own against outbursts of national feeling so long as it has no punitive powers. It will be seen, therefore, that "biothymology" has a very wide range.

In *Nomogenesis or Evolution Determined by Law*<sup>11</sup> LEO BERG, professor of geography in the State University of Leningrad, states the case against Darwinism with much ability and wealth of detailed argument. He contends that evolution does not depend on chance variations and the survival of the fittest in the struggle for existence, but is based on laws, and is in great measure an unfolding of pre-existing rudiments. As Professor D'Arcy Thompson says in his genial introduction, the book is interesting and contains much of recent Russian work, but the views expressed are hardly likely to be universally accepted. It has been admirably translated from the Russian, and, since the last edition, has been supplemented by much new matter. A feature, not always noticeable in foreign books, is the frequent reference to British biologists.

Messrs. Churchill have now issued the *Medical Directory*<sup>12</sup> for 1927. Its general arrangement and appearance are unchanged, and the work as a whole follows the familiar lines which have made it so useful a reference book during the past eighty-two years. The numerical summary of the medical profession, to be found immediately after the table of contents, shows that the number of names in this edition is 52,558, being 1,405 more than in the last. All areas show increases. London has 367 more names, the Provinces 515, Wales 51, Scotland 130, and Ireland 145. The section relating to practitioners registered in this country but living abroad has 275 more names. The only section in which there is a decline is that for the Services, where the total has dropped again, this time from 3,283 to 3,205. Excluding these and the "abroad" entries, nearly one-fifth of the practitioners whose names appear have addresses in the wide London postal area. The directory of dentists which used to form part of this volume was removed two years ago, and the publishers now issue it separately. A section on the spas and climatic health resorts of the British Isles and of New Zealand is again contributed by Dr. R. Fortescue Fox; this appears among the introductory matter. The "late list" (new names and recent changes of address) follows items of miscellaneous information at the end of the directory. Of the work as a whole we need only say that the very high standard of accuracy in previous issues appears to be maintained, and we shall be surprised if daily reference to it during the next twelve months brings to light any errors for which the editors or printers are responsible.

## THE HEALTH OF THE SCHOOL CHILD.

(Continued from p. 1071.)

LAST week we gave an account of the first and more general part of the annual report of the Chief Medical Officer of the Board of Education on the health of the school child. We now propose to give some account of other parts of the report.

### MEDICAL TREATMENT.

There has been during recent years a steady growth in the amount of treatment provided by local education authorities for the common defects, and with this there has been a tendency to widen the scope of treatment. The determining factors have been the needs of the children, the presence or absence of existing facilities for treatment, the possibility of treatment by the private medical practitioner, and finance. New schemes are submitted to the Board of Education; present-day financial conditions require a strict scrutiny of the money available, both local and national. Thus it may happen that the Board is unable to approve proposals which, however desirable, are too costly, and the needs of large numbers of children are still unmet. This is particularly true of conditions where prolonged treatment is required for special defects, and there it is thought voluntary funds should come to the rescue. Contagious skin diseases and external eye defects make up the bulk of the cases dealt with at minor ailment clinics. These minor ailments may do irreparable damage to sight and hearing unless treated early and continuously. Reports show a general decline of scabies and also of ringworm; but common impetigo has not decreased. The treatment of ringworm by x rays has been most effective, and some urban districts report that no cases exist.

### Defective Vision.

Defective vision and its treatment swells the work of the school clinics as much as ever. This year a separate record shows that the cases of squint reported number no fewer than 26,402, or one-sixth of all the cases of defective vision. Note is made of the necessity for the early discovery of these cases of squint if there is to be satisfactory treatment. More attention is being paid to the need for making allowances for the children in the schools, not only by securing satisfactory lighting arrangements in classrooms, but also by modifying the curriculum where necessary to avoid eye-strain. The London County Council's regulations now prohibit the teaching of needlework by artificial light except when the school medical officer is satisfied that the artificial light is sufficient.

A hint of the importance of continuing to wear spectacles and not to abandon them at the end of school life is given in an interesting note by Dr. Joseph of Warrington in respect of 163 children for whom glasses had been provided and who had left school during the year. Among the 27 boys and 30 girls still wearing glasses there were no instances of unemployment, whereas out of 56 boys and 50 girls who had ceased to wear them 6 boys and 10 girls were unemployed.

### Enlarged Tonsils, Adenoids, and Otorrhoea.

Enlarged tonsils or adenoids of a degree sufficient to require treatment are found in about 5 per cent. of unselected school children examined. The incidence differs widely in different places, but this may be due to variations in local standards. Local conditions, however, appear to have some influence, for the condition is more frequent in damp, low-lying districts than in warm, dry, and sunny parts. An illustration of an apparent increase is recorded in London, where the number of routine cases referred for treatment rose from 8,944 in 1924 to 12,876 in 1925—an increase of 44 per cent. This was due partly, not to an increase in the prevalence and severity of the condition, but to an alteration in the standard of diagnosis and increased facilities for treatment, especially in-patient treatment. The total number of children treated by operation throughout the country during the year was 23 per cent. more than in the preceding year. The after-results of operation have been the subject of investigation by several school medical officers; the results as regards the unfavourable symptoms associated with the condition have been generally satisfactory.

A careful analysis of 85 cases followed up after operation by Dr. Cramb of Brighton gave the encouraging result that deafness was cured in 88.5 per cent., and otorrhoea in 90.3 per cent. Experience showed that the principal practical points were:

1. That enlarged tonsils and adenoids may be focal sources of serious infection and therefore require careful attention.
2. That slight conditions do not require operation and should be otherwise treated.
3. That after operation patients should be detained in hospital for at least one night.
4. That following up and supervision are needed in all cases.

For the treatment of otorrhoea by ionization, provision has been made by twenty-six authorities. In London six special centres have been formed. An analysis of 602 cases treated by ionization in eight representative areas shows that 415, or 68.9 per cent., were cured during the year. An excellent account of this method of treatment is supplied by Dr. Alfred Friel, assistant aurist to the London County Council; it should be read by every school doctor and clinical assistant in the aural departments of hospitals. There can be no doubt of the advantage of the successful treatment of these cases of discharging ears. Not only is a most disturbing and foul-smelling discharge removed, but other and greater risks are avoided. The aural surgeon to the Leicester education authority comments upon the decreasing number of cases of mastoid disease largely owing to this increasing care and attention.

"The number of mastoid operations this year was only 13, a further diminution as compared with 1924, when it was 18, and a very considerable difference if we turn back to 1921, when 64 mastoid operations were done. It is doubtful whether the number of these major operations will become still less, considering the large numbers of chronic discharging ears that are always under treatment."

#### *Crippled Children.*

There has been a considerable development during the past year of schemes for the treatment of crippling defects, including provision for hospital treatment, and for after-care clinics, in 85 areas. But there is still need for a great increase in hospital accommodation if crippled children are to be dealt with in comprehensive fashion. It is not practicable to form a national estimate, but local authorities should not find it difficult to ascertain local needs. The problem is not only that of the school child. A large proportion of the crippling has its origin during earlier years, and any effective scheme must take into account children under 5 years of age. The success that has attended the use of heliotherapy in the treatment of certain conditions, especially of rickets, of lupus, and of bone, joint, and glandular tuberculosis, has led to the trial of artificial sunlight for these cases. The biological action of the ultra-violet rays is at present only imperfectly known, but so far experience has shown that the radiations are beneficial in these cases of surgical disease, also some skin conditions and certain cases of general debility. Some account is given of the use of the rays in certain areas. Note is made of some of the risks involved—for example, burns, eye affections, blood changes, unsuitability to febrile cases, liability to headache, nausea, and fatigue. There is much work to be done before it can be held generally suitable for school clinics.

Summing up the section on medical treatment, it is said:

"No new form of treatment is sanctioned by the Board which infringes the principles which have from the commencement governed this work, and to which reference has frequently been made in these reports, viz., that the treatment cannot be better provided otherwise, that it is the most economical method, that the due regard is paid to existing facilities and private medical practice, and that the convenience and welfare of the children, as well as the responsibility of parents and authority, are considered. It is obvious that the continual growth of school clinics calls for vigilance to secure that they do not become mere out-patient departments with their manifold disadvantages and that the treatment provided, whether by general practitioner or whole-time officer, is effectually supervised."

#### THE SCHOOL BUILDING IN RELATION TO HEALTH.

There is a most interesting section on the effect upon health of the school premises. In the earliest days of organized provision of school buildings the one and only guiding principle to which the architect had to work was that furnished by the educationist, but there has since been a steady and increasing influence of ideas of health upon design. Edwin Chadwick, in a small pamphlet published nearly sixty years ago on *Sanitary Principles of School*

*Construction*, showed a modern appreciation of the social and health side of school work. The plan of central hall and surrounding classrooms lent strong support to mechanical systems of ventilation, which were indubitably better than the earlier schools. But mechanical effects had their disadvantages, and these systems have given place to natural ventilation. About 1910 there came the pavilion or cross-ventilated type, the first of which was built by the Staffordshire local education authority at the suggestion of the late Dr. George Reid. The soundness of the principle of the plan was at once recognized, and since then it has become the dominant plan of school building. Of existing buildings it is stated that it is common knowledge that many fail to reach a minimum standard of sanitation and suitability. The Board has recently carried out a survey of elementary schools, with the result that 664 were classified as unsuitable and incapable of improvement, but that a larger number might be reconditioned. Defects pointed out are often of a character that would require little cost to remedy—far less than a new school—and in some cases no expenditure at all, merely the more intelligent use of existing accommodation and appliances.

#### SPECIAL SCHOOLS.

The report contains a very lucid account of the curriculum of the blind school written by Dr. Eichholz. It is found that there is sufficient accommodation for blind children, but not enough for the partially blind, and no general arrangements for the after-care of the partially blind. In London, however, of 437 children who left the myope classes in 1921 and 1923, as many as 304, or 69 per cent., were known to be employed; and 49, or 11 per cent., were unemployed but employable; 20, or 5 per cent., were under further training; of 64, or 15 per cent., no record was procurable. In a summary of conclusions on the training of the blind, it is stated that a "main requirement" is "Provision of residential accommodation in preference to day schools for blind scholars of all ages—in the interest of true nurture of health; and of outlook and proper setting for educational training."

This sweeping statement is in striking contrast to the finding with regard to the education of mental defectives. For these no such stereotyped generalization is advocated. We read:

Experience in this country, and indeed elsewhere, also suggests that the "special school" is not the only, nor always the most effective, way of extracting and developing citizenship out of unlikely material. For the worst type of case it is not proving as serviceable as was formerly believed. In such cases custody, occupation, and segregation are generally necessary. For the higher grade defective special educational training is, however, the obvious development. In the rural districts where institutional training is impracticable or unavailable, much may be done by domestic supervision and employment in suitable forms of agricultural labour. *Each case must be adjudicated on its merits, and patient, intensive, and experimental methods are our only hope, followed up by consistent after-care.*

The italics in this passage are ours; the statement italicized should be related to the generalization thought desirable for the blind.

#### CONCLUSION.

In concluding his report, Sir George Newman gives an answer to the question he put at the beginning: Is the service worth the cost? He concludes that it is. In the year two and a half millions of children were medically inspected, a million cases of defect were treated, three-quarters of a million more had dental treatment, all the children in the schools have been regularly supervised as regards personal cleanliness, and in every area much has been done to encourage good habits and good physical training. "All this cannot have been without beneficial effect. Indeed, we can specify more exactly what the effect has been." Scabies, rickets, and ringworm are vanishing. Gross forms of deformity from malnutrition and congenital syphilis are rare. And on the positive side the child who is leaving school at 14 is better physically in every way than was the "leaver" of twenty years ago, and this child is less handicapped than formerly in obtaining and keeping employment. The prompt treatment of ailments has improved school attendance, and the mental "educability" has been raised. Another unlooked-for result is the better appreciation of fresh air. The English people are becoming an open-air race.

# British Medical Journal.

SATURDAY, DECEMBER 11TH, 1926.

## THE NOMENCLATURE OF PARASITOLOGY.

Nearly sixteen years ago (December 24th, 1910, p. 1989) the BRITISH MEDICAL JOURNAL drew attention to the chaotic state of zoological nomenclature, especially as it affected medicine, and stated that: "What the mass of zoologists want is a system which will secure stability, which will obviate the necessity for antiquarian research, which, at the same time, will reject enigmatical descriptions, and will insist on the reference of all species to a central authority." It is interesting to note that Professor R. T. Leiper, F.R.S., in his presidential address to the Section of Tropical Diseases and Parasitology of the Royal Society of Medicine (which is reported elsewhere in this issue), expressed the view that zoological nomenclature as applied to medicine is producing the utmost confusion, and interfering to a very considerable extent with the teaching of the subject. In 1910 we stated that "assiduous individuals have spent their days and nights ransacking musty archives and long-forgotten tomes. From these they have extracted a galaxy of paradoxically new yet old names which they have tacked on to the familiar friends of our youth." These archaeo-parasitologists are still busy, not only in helminthology, as has been so vividly demonstrated by Professor Leiper, but in all those ancillary medical sciences which come under the control of the biologist. We have all learnt that the virus of yellow fever is carried by the mosquito *Stegomyia fasciata*, yet we read nowadays that the vector is *Aedes aegypti*. We are acquainted with the helminthic parasite *Filaria bancrofti* and its association with elephantiasis, yet we are disconcerted to learn of a disease, which seems very similar, caused by *Wuchereria wuchereria*, and it is only after considerable research that we discover that the second of each of these combinations is but a new name, the old having been changed, not by deed-poll, but by the activities of the excavators.

The cause of this confusion is the "law of priority" of the International Rules of Nomenclature, which, strictly applied, causes names in forgotten tomes and buried minutes to be resurrected and foisted on an unwilling body of workers. The law is, however, somewhat peculiar in its application. Old writers habitually wrote in Latin, and their latinized popular vernacular names necessarily resembled in outward form the binominal system, although, in fact, their users had no intention of being thus understood. Thus, for example, an old writer, Werner by name, wished to describe a round-worm from the dog, and he called it the lumbricoid of the dog, or, in Latin, *Lumbricus canis*. This has been seized upon by our excavators and hailed as a specific binominal combination, which, as anyone can see, it is not. And yet our ultra-modern textbook writers have adopted it without inquiry, and rendered nomenclature even more confounded. A similar state of affairs exists among the spirochaetes, although a recent authority has simplified matters by abruptly discarding all the fancy names and placing the whole lot in the one old well known genus. The fungi are similar, and a spate of new generic names,

hailing from America, threatens to reduce bacteriology to a state of utter confusion; yet the astonishing plethora of letters and strains, of paras and pseudos, makes that subject sufficiently complicated for the ordinary reader.

Surely this is all unnecessary. After all, the name is of little value by itself, provided we can understand its connotation. Professor Leiper has suggested two alternative remedies: either we should adopt a special medical terminology for the parasites of importance—a course which is open to obvious objections and should only be adopted if the second fail—or we should stabilize the well known names of the parasites without regard to the law of priority and without reference to ancient minutes and abstracts, or to modern descriptions and paragraphs which form the source from which many of these replacement names have been taken. Professor Leiper appears to suggest that some independent body might be willing to undertake the duty of preparing an agreed list of names of parasites, animal and vegetable, in consultation with medical teachers and writers, so that harassed readers, and teachers also, may escape from the labyrinth wherein the nomenclators have cast them. This could be done with the active co-operation, where found desirable, of zoologists and botanists, who even now have the power under the international rules to insist that, where these rules operate too arbitrarily and cause too much confusion by their strict application, exceptions should be made. This has already been done in some instances, and there is no reason why the creation of such a list of "fiat" names should be beyond the forensic powers of our biological and medical legislators. We fear, however, that Professor Leiper's plea will bring him neither tranquillity nor peace, unless it be that of the spirit which rides the storm.

## POLIOMYELITIS IN INSTITUTIONS.

The controversy in the public press regarding the measure of dispersal adopted at Uppingham School for dealing with the occurrence of cases of poliomyelitis there, and the recent occurrence of cases at the Royal Military Academy, Woolwich, has brought into prominence the divergent views of members of the medical profession on the question of dispersal or isolation of institutions when cases of this nature arise. The latter method has been adopted at Woolwich, as it was in boarding schools at Broadstairs, but the Uppingham and Woolwich conditions are not exactly comparable. Poliomyelitis is more widely spread than usual throughout the country, and isolated cases are occurring from time to time in many places. It is not surprising, therefore, that one or two schoolboys at Uppingham and cadets at Woolwich should have acquired the disease.

The first case at the Royal Military Academy occurred at the end of October. The early symptoms were those of mild influenza, but on the development of paresis of the palate an examination was made of the throat exudate at the Queen Alexandra Military Hospital, Millbank, when a micro-organism similar morphologically to the bacillus of diphtheria was isolated, although no culture was obtainable. The patient was accordingly sent to the London Fever Hospital as a case of diphtheria, but eventually, after a further extension of the paresis, the diagnosis of poliomyelitis was made. In the meantime a cadet at Woolwich belonging to the same term, who had been in constant association with the first case, although each had a separate room, was admitted to the cadet

hospital with influenzal symptoms on November 4th; on the appearance of paresis of the arm and leg the case was diagnosed as one of poliomyelitis and transferred to Queen Alexandra's Military Hospital. No other case occurred until November 21st, when another cadet, also of the same term, developed symptoms of influenza when at home on week-end leave. He returned to Woolwich on November 26th, and was placed in hospital under observation. Three days later he developed slight paresis of the deltoid, and the diagnosis of poliomyelitis was made. Since then another case has occurred in Edinburgh in an officer of a battery that was transferred from Woolwich on November 10th.

The measures taken from the first by the army medical authorities followed the usual lines on the occurrence of infectious disease of this nature, but more extensive restrictions and isolation have been enforced after a consultation last week with members of the Army Medical Advisory Board and the Hygiene and Pathological Committees. The cadets and staff are confined as far as possible to the academy grounds. Rugby football and other recreations involving crowding together are stopped, and cadets are not allowed to work in one another's rooms. With the exception of the first-term cadets, who have a comparatively large room for every two, the cadets have each a separate room. All feeding utensils are sterilized after use. There is a daily medical inspection by the officer of the R.A.M.C. in medical charge; and each cadet has to gargle thrice daily with 1 in 5,000 potassium permanganate in normal saline solution. Football matches and competitions of every kind with other institutions have been cancelled. These indicate the general measures adopted for isolating the institution from the outside community and for preventing spread of infection within it. Although cadets are thus restricted to the academy grounds, we understand that parents have been informed that, if they so desire, they may remove a cadet to his home, but are recommended not to do so.

Epidemics of poliomyelitis among young adults in military institutions are not uncommon, and in the years before the war were of considerable gravity in some Continental barracks, so that the importance of thorough measures for dealing with early cases in institutions such as the R.M.A. and R.M.C. should not be minimized. The age of the cadets is roughly that of university undergraduates; there are 205 at present at the Royal Military Academy, and 465 at the Royal Military College, Sandhurst, where similar restrictions have been imposed in order to prevent risk of infection being introduced from the local civilian population, amongst whom three cases have been reported. There is, however, nothing in the extent or nature of the cases that have occurred either at Uppingham or Woolwich to create alarm, although the publicity given to them has had the effect of perhaps exaggerating their importance. Fortunately we are at a season of the year when the incidence of the disease usually declines.

#### MR. COLERIDGE ON DIABETES.

In *The Pilgrim's Progress* we read of certain giants, one of whom has been dead many a day, "and as for the other, though he be yet alive, he is, by reason of age, and also of the many shrewd brushes that he met with in his younger days, grown so crazy and stiff in his joints, that he can now do little more than sit in his cave's mouth, grinning at pilgrims as they go by, and biting his nails because he cannot come at them."

There was, perhaps, a time when the antivivisection giant was more formidable to pilgrims than he is to-day, when there was a real risk that the progress of knowledge might be arrested at the bidding of this giant, but that was a good many years ago, and Mr. Stephen Coleridge's revival of the old play (in the *Times*) is instructive without being successfully offensive. The assumption that men of science have no sympathy with or affection for dogs needs no comment, but Mr. Coleridge's reasoning about the value of insulin in diabetes merits a few words of amplification. "I harbour the belief," he writes, "that if a treatment fails to lower the death rate per million living persons it cannot be doing any good as a means of preventing people from dying of a disease."

Let us see where this aphorism leads us. Many years ago the surgical treatment of cancer of the breast was one of the gloomiest pages in our textbooks. Thanks to Halsted and other great surgeons, the technique of the operation was revolutionized. Halsted believed that when cases were treated early 75 per cent. of the patients might live three years. Many thought this too good to be true. We now know it to have been a modest estimate. Within the last year an official report on experience in this country<sup>1</sup> has recorded that as many as 90 per cent. may survive, not three, but ten years—results which are, as the author says, "at once a challenge to pessimism and a stimulus to efforts to secure operative treatment at the earliest possible stage of the disease." But the death rate from cancer of the breast is not falling, it is rising. The inferences the ordinary educated man would draw (even the ordinary antivivisectionist, for the surgery of the breast is the business of surgeons, not of hard-hearted Fellows of the Royal Society) are, first, that the actual incidence of cancer of the breast may be increasing; and second, that the proportion of sufferers who reach the surgeon's hands early enough to be effectively treated is still too small to influence the total mortality. These conclusions would lead him to spread abroad the knowledge of what surgery can do, in the hope that lives now sacrificed might be saved. But, according to Mr. Coleridge's logic, all this is foolish. The Registrar-General's figures show that cancer of the breast is increasing; we must therefore "harbour the belief" that Halsted was a self-deceiver, that the evidence published by the Ministry of Health is worthless, and that the less women with cancer of the breast have to do with the surgeon the better, for the death rate has not been lowered. *Per contra*, we shall perhaps infer that as infant mortality since 1918 has never regained the pre-war level, the best means of infant welfare are great European wars.

But, in fact, this kind of statistical "reasoning," farcical as it is when applied to a surgical instance, is not so absurd as in the instance of diabetes. There has been a certain regularity of increase in the death rate from cancer of the breast. But the death rates from diabetes have fluctuated in a manner which statisticians have not yet explained. There have been changes which can in no way be related to methods of treatment. Dr. Stevenson<sup>2</sup> has called attention to the changed relation of the sexes. Before 1920 the death rate on males was always higher than upon females; since 1920 this has been reversed. Dr. Young and Mr. Russell<sup>3</sup> note other peculiar features of the

<sup>1</sup> Ministry of Health: *Reports on Public Health and Medical Subjects*, No. 31. A Report on the Late Results of Operation for Cancer of the Breast. London, 1926.

<sup>2</sup> The Registrar-General's *Statistical Review of England and Wales for the Year 1925*. Text, pp. 65-67.

<sup>3</sup> *Quarterly Journal of Medicine*, vol. xx, 1926. Pp. 87 et seq.

statistics. The simple fact is that enough is not known of the etiology of diabetes to enable these statistics to be fully analysed. Years ago it was pointed out that statistically diabetes was increasing; various attempts have been made to associate this increase with that of cancer, but they have not thrown any light upon the subject, yet Mr. Coleridge has not refrained from handling the statistics in the crudest possible manner. Etiologically considered, diabetes is an unsolved epidemiological problem, but ignorance of one side of a problem must not be made an excuse for denying that we have knowledge of a different aspect of it—the clinical. Dr. Elliott and Sir Walter Fletcher term this appeal to ignorance "pitiable casuistry." That is too charitable a judgement. Casuistry requires some intellectual subtilty. This is the *ignoratio elenchi* of a schoolboy set out in pompous language. It is shown by the direct clinical observations of independent physicians, basing themselves upon a statistically adequate number of instances, that a particular method of treatment is successful. No attempt is made to refute those observations by the submission of similar clinical statistics pointing to a different result. Instead, statistics relevant to a totally different issue are produced.

What would a judge say to a prosecuting counsel who attempted to refute specific evidence that the prisoner at the bar had not committed a particular murder by quoting statistics to show that undetected crimes of violence are increasing?

#### LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

A MEETING of the court of governors of the London School of Hygiene and Tropical Medicine, when Sir Holburt Waring, chairman, presided, was held on December 7th in the Council Room of the House of the British Medical Association. A unanimous vote of condolence with the widow of Dr. J. C. McVail was passed. The second annual report of the board of management included a detailed description by Dr. Andrew Balfour (director) of the work of the tropical division for the year ending July 31st, 1926. The average number of students each term had been rather higher than in the previous year, and the total was satisfactory in view of the increased length of the course and the higher fee. Emphasis was laid on the necessity of safeguarding the clinical side of tropical diseases at the school, inasmuch as the Seamen's Hospital Society might not continue to maintain the hospital at Endsleigh Gardens for more than a limited period. If and when it was closed the school would be deprived of the long-existing facilities for clinical and pathological study. The Minister of Health had appointed a committee with broad terms of reference, under the chairmanship of Sir Alfred Mond, to consider how the emergency might be met. The board had decided to apply the capital of the Milner Research Fund, as well as the income, to the extension of research work. On the invitation of the Royal Society the board had nominated Dr. A. W. Grace, a former student of the school, to undertake research in the West Indies into the bacterial complications of filariasis. Towards the cost of this expedition the school was making a contribution out of the Milner Research Fund of £500 a year for a period of two years and possibly more. It was announced that the work of the Institute of Agricultural Parasitology was being expanded under the direction of Professor Leiper, and that Winches Farm was nearing completion as a field station, the cost of maintenance of which would be met out of funds provided by the Development Commissioners at the instance of the Minister of Agriculture. Sir William Hodgson suggested

that this important side of the research activities of the school might be further extended, and that some aspects of foot-and-mouth disease might be considered. The chairman stated that the deficit taken over with the London School of Tropical Medicine on August 1st, 1924, had now been entirely wiped out, partly through an extra grant of £5,000 a year from the University Grants Committee, and partly by a generous donation from the executors of the late Mr. Alfred de Rothschild. Warning was given that the work of the tropical division would be inevitably carried on at a loss if the amount of available Exchequer assistance remained at £2,200, unless there was a substantial increase in the endowments and annual subscriptions; additional funds might, perhaps, be obtained from colonial Governments and commercial sources. Representations had been made through the Minister of Health to the Treasury early in 1925 that the commitment of £25,000 a year entered into by the Government at the time of acceptance of the gift from the Rockefeller Trustees would fall far short of the requirements of the staffing and upkeep of the school when fully functioning in the new building. The organization of a great graphic museum is in the hands of Sir Wilfred Beveridge. An account of the proceeding on the occasion of the laying of the foundation stone of the new building by Mr. Neville Chamberlain, which we reported on July 10th (p. 75), was presented to the court of governors. It was announced that the progress in building had been seriously delayed by the dispute in the coal-mining industry, but Sir Walter Fletcher announced that the Education Committee was exploring a possibility of commencing the teaching of hygiene in temporary premises, in view of the demand for trained research workers manifested in the proceedings of the recent Imperial Conference, a demand to meet which the school was primarily established.

#### RHEUMATIC INFECTION IN SCHOOL CHILDREN.

IN his annual report for 1925 the Chief Medical Officer of the Board of Education returns to the subject of rheumatism in school children, which was afforded considerable space in the volume for the previous year. As usual, the report deals particularly with the work of the school medical service, and we do not look in vain for information such as could be gathered only by such a service. Several eminently useful facts are noted. Dr. Menzies, for instance, estimates that there are not fewer than 10,000 school children in London who are suffering, or have suffered, from rheumatic symptoms, and that from 600 to 700 children are absent from school for long periods on account of this infection. These figures represent 25 per cent. of the chronic invalidity among children. Again, we learn that over 1,000 children suffering from rheumatism and heart affections are being educated in the London schools for the physically defective. An inquiry addressed in respect of thirty open-air day schools elicited the verdict that rheumatism of any severity was unsuitable for treatment on such lines—a conclusion that most workers in metropolitan hospitals will endorse. When we consider the problem of the early detection of rheumatism and the prevention of heart disease, we must own that the assistance given by the school medical service is at present very slight, and the number of cases detected and referred to hospitals by it extremely few. This is due largely to the infrequency of the periodic examinations made. In the report for 1924 there were laid down (pp. 104-107) some excellent suggestions for local education authorities whereby an improvement might result. In the present report these suggested "lines of action" are repeated, and "considerable advance" along them is reported. Further details would have made pleasant reading. The problem of rheumatism among the children of this country is a large matter, and to set going any organized scheme of prevention on a big

scale will take both time and patience. Yet it is all to the good that the gravity of the infection as a national disease is increasingly recognized, and we do not doubt that as the medical profession as a whole, and the hospitals in particular, set about to deal with the disease with greater stringency, the school medical service will rise to the occasion and give valuable aid in co-operating with them.

#### TREATMENT OF CANCER BY LEAD.

WE publish elsewhere in this issue (p. 1135) a note by Dr. R. G. Canti of the observations he made while attending in Liverpool a demonstration given last week of the method of treating cancer by lead. Similar demonstrations, some of them extending over a longer period, have been given on several occasions, and one of these Dr. Canti had attended, so that he was prepared to take full advantage of the rather strenuous programme planned by the Liverpool Cancer Research Organization for Tuesday, November 30th. It had been arranged in order to meet the convenience of a deputation from the Executive Committee of the British Empire Cancer Campaign, and Professor Blair Bell was good enough to invite the BRITISH MEDICAL JOURNAL to send a representative. We are much indebted to Dr. Canti for consenting to accept this invitation on our behalf. The deputation consisted of Mr. P. Lockhart-Mummery (chairman of the Executive Council, Sir C. Gordon-Watson (chairman of the Preliminary Inquiry Committee), Professor Lazarus-Barlow (chairman of the Intelligence Committee), Sir William Willcox and Mr. Sampson Handley (members of the Executive Committee), Dr. Hopwood (Professor of Physics in St. Bartholomew's Hospital Medical College, and a member of the Radiology Committee) and Mr. E. J. C. Chapman (secretary). The deputation will make its report to the Scientific Advisory Committee, which will in due course transmit it, with any observations it may deem proper, to the Grand Council of the Campaign, and not until that body has considered it will anything be published. We are informed, however, that all the members of the deputation were impressed by the sincerity of the work, and formed the opinion that relief had been given to a considerable number of sufferers. The principles upon which the treatment rests, the histological changes found in cancerous tissues treated with lead, the clinical effects of lead, and the nature and purpose of the Liverpool Cancer Research Organization, were fully described in the report of the proceedings on the subject in the Section of Medicine at the Annual Meeting of the British Medical Association this year, published in our issue of November 20th (p. 919). We understand that arrangements are being made at St. Bartholomew's Hospital for carrying out further researches into the efficacy of lead in cancer.

#### RADIUM AND UTERINE CANCER.

THE London Association of the Medical Women's Federation has established a Cancer Research Committee, and its work during the first six months of its activities has been recorded in a report to the British Empire Cancer Campaign, entitled "The radium treatment of cancer of the uterus." Deaths from cancer of the uterus number more than 4,000 a year in England and Wales alone. In February, 1925, the women's committee was lent 300 mg. of radium bromide by the Medical Research Council. The work has been carried out under a subcommittee of all the members of the gynaecological staffs of the women's hospitals co-operating. A summary of the work already done in this connexion, which has from time to time been recorded in the pages of the JOURNAL, is followed by a useful bibliography. It was decided to choose so far as possible cases of cancer of the cervix for treatment, since the disease is localized for some time at the site of origin,

and in comparatively few instances are the pelvic glands invaded. After discussing the various modes of application, the reasons for the choice of the methods in favour at the Radium-Hemmet, Stockholm, are given. In it cross-radiation is obtained. One or two tubes are inserted into the cavity of the uterus, and are supplemented by radiation from applicators placed in the vault of the vagina. Not the least of the advantages of the method is that it can be applied in many cases without a general anaesthetic, with trifling disturbance to the patient, and with no injury to the tissues other than that caused by the radium. Comparatively heavy doses of radiation were given in preference to weak doses, which, it is considered, have been shown to be not only ineffectual, but even harmful. After appropriate preparation of the patient and disinfection of the parts, the radium is inserted and kept in place by a firm gauze pack, which also serves to protect the vaginal mucous membrane and prevent too close contact of the radium with the bladder and rectum. Three applications were made, the second one week after the first, and the third two weeks after the second. Each application lasted twenty-two hours. The total dose varied between 5,000 and 7,500 mg. hours. An account is given of 42 cases of carcinoma of the cervix so treated. Of these, 29 were inoperable cases: 6 cases had completed treatment only recently; 14 treated for six months are symptom-free, and no local disease is apparent; 4 are symptom-free but evidence of disease is present; 4 are going downhill; 1 died three months after radiation without recurrence of local symptoms. Headache is complained of by the majority of the patients, but it is not severe; nausea and vomiting, chiefly after an anaesthetic, were observed, but the vomiting ceased immediately the radium was removed. There is transient rise of temperature, and diarrhoea is common. In one case there was pyometra, and in another peritonitis due to an abscess. This report on radium treatment, together with similar communications from other organizations, is included in the annual report of the Medical Research Council on the medical uses of radium, of which an account is given on page 1136 of this issue.

#### "ACCIDENT PRONENESS."

REPORT No. 38 of the Industrial Fatigue Research Board is a "Psychological study of individual differences in accident rates," by Messrs. Eric Farmer and E. G. Chambers, investigators to the Board. The investigations were made on 611 boy apprentices employed in naval dockyard or Royal Air Force shop work, and on 40 women engaged in manufacturing and packing sweets. The investigators came to the conclusion that inequality in accident liability among individual workers was not solely determined by external factors or by chance. In an appreciable degree the inequality was due to measurable individual differences. In the pursuit of the problem it was found necessary to coin and define several new terms. Accidents were more frequent in those with poor "aesthetico-kinetic co-ordination," a term invented to avoid the use of "sensori-motor" or "neuro-muscular," which have already well defined scientific meanings. Similarly, "accident proneness" is used to mean a personal idiosyncrasy predisposing the individual to a relatively high accident rate, while "accident liability" includes all the factors determining accident rate. Nervous instability was found to be related to frequency of accident, but no relation appeared to exist between accidents and the higher intellectual processes. There was slight indication that the accident-prone were industrially inefficient and more liable to report sick. The authors are contemptuous of those who say that accidents are due to carelessness, and who, when asked to define carelessness, leave little doubt that they simply mean having an undue number of accidents. They are careful,

however, to warn us not to make accident incidence *per se* a measure of accident proneness. They note also that at present the reliability of the tests they used has not been established, and that until this is done the tests cannot safely be used for prognosticating the accident proneness of individuals. It will be seen, therefore, that the matter, like some other subjects under consideration by the Industrial Fatigue Research Board, is still in the pioneer stage. With further study it is possible that the ideal of the investigators may be attained, and arrangements may be made to place unsafe persons in occupations involving the minimum of risk to themselves and others. But the ordinary man, we expect, will long continue to use the term "carelessness" in preference to "accident proneness."

#### FRACTURE OF THE NECK OF THE THIGH BONE IN ADULTS.

THE unfortunate elderly people who suffer fracture of the neck of the femur are in too many cases much to be pitied, for the pain and disability which attend upon it when not successfully treated are such as to embitter the evening of life and compel an otherwise sound person to become an invalid. The Section of Orthopaedics of the Royal Society of Medicine did well, therefore, to choose this subject for discussion at its meeting on Tuesday evening last. The subject was introduced by Mr. S. L. Higgs, and a number of speakers well qualified by their experience kept up the debate until a late hour. As regards treatment, two main questions presented themselves: first, what is the best routine treatment which could and ought to be followed by practitioners in general; and, secondly, what is the best course to pursue in a hospital equipped with the necessary skilled staff and appliances. The balance of opinion was in favour of Whitman's method of full abduction, traction, and rotation inwards, maintained by a long plaster-of-Paris spica in the first case, while there was a lesser approach to unanimity as to the ideal method of treatment in an orthopaedic hospital or department. Mr. Hey Groves, whose work in this connexion and whose recent lecture before the Royal College of Surgeons are well known, advocated open operation and fixation of the fragments with beef-bone pegs, for only by exposing the site of injury to ocular inspection can one be sure that the fragments are not separated by soft tissues, which complication is so fruitful a cause of non-union in the fracture of the patella and other bones. There seems little doubt that in fracture of the neck of the femur, as in others, the most important and the commonest cause of non-union is the separation of the fractured surfaces from one another. Since the introduction of radiography we are in possession of knowledge as to the position of the fragments which was unobtainable a generation ago, but, as was pointed out, the information so given is imperfect, and it is only by the use of the stereoscope that we can obtain any knowledge of the relative position of the fractured surfaces in an antero-posterior plane. Thus an appearance of impaction may be conveyed by the shadows of structures which may actually be separated by an inch or more. Similarly, we may be deceived into assuming that almost complete absorption of the femoral neck has occurred when its disappearance is really in whole or in part due to external rotation of the femur. No speaker maintained that these injuries are in general well treated in our great teaching hospitals, but speaker after speaker, some of whom are on the staffs of such hospitals, admitted that if treated at all they were not so dealt with as to instruct students and future practitioners in efficient, up-to-date methods. Unfortunately, this reproach is too widely justifiable as regards fractures in general, as well as regards this particular injury. It is also worthy of remark that the bugbear of surgeons of thirty years ago—hypostatic pneumonia and the dangers

of prolonged recumbency in elderly patients—is no longer feared. Such scant reference as was made to it consisted in its dismissal as a baseless fear. Better methods of nursing and dieting, as well as improved orthopaedic appliances, are probably to be thanked for this.

#### STANDARDIZATION OF DISINFECTANTS.

AN addendum to the report of the Medical and Health Department of Western Australia for 1923-24 presents an account of the examination of certain disinfectants by Dr. John Dale and Mr. J. G. C. Campbell. The work, which includes both chemical and bacteriological tests, was carried out in the laboratory of the Public Health Department at Perth, W.A., during the year 1921 on a series of disinfectants tendered by manufacturers for hospitals and Government departments. They were chiefly coal-tar preparations of the emulsifying and non-emulsifying groups. In their bacteriological tests the authors adopted the suggestion of Chick and Martin to test germicidal power in the presence of organic matter. They found that its efficacy was enhanced by sewage and not obviously depressed by 50 per cent. urine. Blood serum in 50 per cent. concentration produced only a slight depreciation of germicidal power, and put a more marked one. A control series of tubes containing a standard disinfectant was included in each day's experiments. Carbolic acid was used as the standard at first, but was discarded later in favour of sanitas sypol, a preparation containing 50 per cent. phenol. Among the conclusions reached are that cresol soap solutions are effective in proportion to their content of phenols as shown by chemical analysis, and that the presence of organic matter calls for an increase of strength. The ratios of increase are: for pure carbolic acid 1.4, for cresol soap solutions 2.4, and for emulsions 8.2. The coefficients found for the coal-tar disinfectants and their depreciation factors are stated in tabular form. Chick's observation that the depreciation of the emulsifying group is much greater than that of the non-emulsifying group is confirmed. No information is given as to the purity of the phenol contained in sanitas sypol. Had the authors used absolutely pure phenol at first they might possibly have retained it as a standard in preference to a member of the lysol class. This painstaking and thorough investigation has rendered useful service by confirming certain conclusions reached by previous workers. It should prove of much value also by affording guidance to the Government of Western Australia and others in the choice and purchase of suitable disinfectants. In some instances it does not sustain the claims made by advertisers.

#### HEALTH OF ALL NATIONS.

THE Health Committee of the League of Nations, which was appointed on a three years' mandate, held its concluding regular session at Geneva last month. From the reports submitted to it by the special commissions to which it had remitted inquiries on various health problems some interesting features emerge. The Cancer Commission has established that the differences of mortality from cancer of the breast and uterus observed in different countries are genuine, and are not to be explained by local differences in diagnosis, registration, and the like. It has found no association between race and cancer mortality in certain European countries investigated. It thinks that the efficacy of early operation should be more generally recognized. The Permanent Standards Commission, which has studied the question of international agreement on methods of determining the activity of biological products, reports that for antidipteria serum the national standards are now identical. For antitetanus serum the international unit is defined as double the American unit,

and the State Serum Institute of Denmark is to collate national standards in order to ensure conformity. The Permanent Standards Commission is also of the opinion that there is a need for further study on the standardization of antidyserentary serum and tuberculin, and on the recent specific methods for the diagnosis, treatment, and immunization of scarlet fever, and views with satisfaction the world-wide use of the international standard for insulin. The Health Committee decided that the Malaria Commission should continue, and that the malaria courses at the Institutes of Tropical Medicine in London, Paris, and Hamburg should be repeated in 1927. It approved the wish of the Conference of Child Welfare Experts that information should be obtained as to the instructions given in various countries to students of medicine, nurses, midwives, and district nurses on infant welfare and hygiene. The topics of school hygiene, international nomenclature of causes of death, public health administration, and health insurance also engaged the attention of the committee. The report of the medical director of the Epidemiological Intelligence Service indicated that Albania, Chili, China, Costa Rica, Luxemburg, Peru, Anglo-Egyptian Sudan, and Transjordanian had been added to the list of countries supplying information. The Epidemiological Bureau at Singapore is in working order, and receives reports regularly from 112 stations in Asia, Australasia, and East Africa. From these transactions, which will be reported to the December session of the League, it is plain that the activities of the Health Committee have ranged both far and wide. Some of its work makes an obvious appeal. An intelligence service receiving regular epidemiological reports from practically every country in the world which is capable of preparing returns must impress the minds of all. The value of its work on the standardization of curative serums and insulin will be cordially recognized by the medical profession, though fully appreciated perhaps only by experts in these particular fields. But in all its enterprises, whether simple or complex, the committee appears to be building securely, and by drawing together scientists of so many countries in the common interests of all it is helping to promote that comity between all nations which is a primary object of the League.

#### NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.

ABOUT two months ago the National Association for the Prevention of Tuberculosis became the tenant of rooms in one of the houses which have recently come into the possession of the British Medical Association at the corner of Tavistock Square. It holds its council and committee meetings in the House of the Association, and the vice-chairman of its council is Sir Robert Philip, President-Elect of the Association. The address of the National Association is 19, Tavistock Square, W.C.1. Its annual report reviews the events of the year, including the annual conference at Glasgow last July, which was reported in our columns at the time (July 10th, p. 66). In an appendix to the report the working of the Burrow Hill Colony, in its third year, is described by Dr. A. H. Macpherson, the resident medical superintendent. The number of men in residence at the beginning of 1925 was 43, at its end 63. There were 214 admissions during the year: of these 139 were ex-service men, of whom 12 were admitted for systematic training. Convalescent patients are largely employed in occupational work in the colony's market garden and grounds: it also has a farm, with cows, horses, pigs, and poultry, and a number of men have been trained in the pig and poultry section. The cows, which are tubercle-free, yielded a supply of milk ample for the colony, which has also a carpentry and joinery department; the men there under training did work for the institution, and also made

and erected portable buildings, fencing, and gates for local residents. In March, 1925, inquiries were sent to 90 men who had completed their course of training; 71 replied. Of these 25 were following the occupation for which they had been trained, 12 some other occupation, and 13 had been unable to obtain work; 8 had been on treatment allowance since leaving the colony; 8 had relapsed after beginning to work; 1 had emigrated to Australia; and 4 had died. Of the 194 patients who ceased to be residents during the year 150 improved, 36 experienced no change, 6 became worse, and 2 died. Another activity of the National Association which is perhaps not as well known to the medical profession as it deserves is the set of films it possesses; these are described in an appendix, and are of a popular character; one shows the production of certified milk, and another the life and work at the Burrow Hill Colony. A third appendix gives a list of lantern slides, statistical and bacteriological, of non-pulmonary tuberculosis, and of the cripple institutions at Alton and Hayling Island, of Rollier's sun school at Leysin, and of certain sanatoriums and open-air schools. Both the films and the slides can be hired on terms which can be obtained on application to the secretary.

#### HEALTH AND WELFARE OF SEAMEN.

LAST summer an international conference on the health and welfare of merchant seamen was held at Oslo under the auspices of the Norwegian Red Cross Society and the League of Red Cross Societies. We published a very full account of its proceedings, and printed the resolutions containing the recommendations at which it arrived, in our issue of July 31st, 1926 (p. 205). The official report has now been published by the League of Red Cross Societies (2, Avenue Vélasquez, Paris; price 2s. 6d.). One of the chief recommendations was that bureaux should be established in all seaports throughout the world, to furnish either treatment or information as to where medical advice and treatment could be secured, postal facilities, and particulars of local recreations and social facilities, and sleeping accommodation. It also invited the League of Red Cross Societies to co-operate with the International Labour Office, the Health Organization of the League of Nations, and other similar organizations, in appointing a standing committee on the welfare of seamen; it would investigate facilities for the medical treatment of seamen, including the standardization of ships' medicine chests, the issue of manuals, the preparation of a wireless code for medical consultations at sea; it would also take steps to forward the education of ships' officers in first aid, and generally to promote health propaganda among seamen and to improve welfare conditions on board and in port. The first part of the report contains an account of the proceedings at the conference, and the second data on legislation and other measures for the protection of seamen.

#### THE HASTINGS LECTURE.

SIR BERKELEY MOYNIHAN, Bt., President of the Royal College of Surgeons, will deliver the Hastings Lecture of the British Medical Association in the Great Hall of the Association's House, on Monday, January 24th, when the Minister of Health, Mr. Neville Chamberlain, will take the chair at 8 p.m. After the lecture questions and a short discussion will follow. The lecture is intended for the general public, and is thus an extension of the practice of the Association to arrange a public lecture at its Annual Meetings. Admission will be free, and tickets can be obtained from the Financial Secretary, British Medical Association House, Tavistock Square, London, W.C.1. The subject Sir Berkeley Moynihan has selected is "Cancer and how to fight it."

## LEAD TREATMENT OF CANCER.

ACCOUNT OF A DEMONSTRATION BY THE LIVERPOOL MEDICAL RESEARCH ORGANIZATION.

BY

R. G. CANTI, M.D. CANTAB.,

BACTERIOLOGIST TO ST. BARTHOLOMEW'S HOSPITAL AND LECTURER IN BACTERIOLOGY IN THE MEDICAL COLLEGE.

On November 30th, 1926, a demonstration was given at Liverpool to representatives of the British Empire Cancer Campaign and others interested in the lead treatment of cancer. After introductory remarks by Professor Blair Bell on the history of the organization and the rationale of the treatment, short addresses were given by Professors Dilling, Glynn, and Lewis, and Drs. Brooks, Cunningham, Jowett, and Millett, on their various subjects. The nature of the physico-chemical and pharmacological research at present being undertaken was fully entered into, and the details of the chemical manufacture of the lead preparation were fully demonstrated in the laboratories. Visits were made to the Royal Infirmary, the Northern Hospital, and to the laboratories and nursing homes in Rodney Street, where 49 cases had been collected for clinical examination. The histories of these cases were fully entered into, and the histological preparations (which are systematically taken), microphotographs, ordinary photographs, and radiographs of the cases were shown.

The organization has already been fully described elsewhere (BRITISH MEDICAL JOURNAL, November 20th), but it is to be noted that apart from some monetary help received from outside sources the investigation is to a large extent self-supporting. All fees collected from patients for consultations, operations, biochemical examinations, injections, and nursing-home accommodation are received by the committee, and this body defrays the expenses in connexion with both the clinical work and the laboratory investigations.

The co-operation and "team" spirit of the various workers in widely different fields were the admiration of those present, and it may confidently be said that this centralization of control and close co-ordination of workers has set an example to the whole country.

### THE TREATMENT.

The rationale of lead treatment is now well known, and is based on Professor Blair Bell's work on the action of lead on the syncytial cells of chorionic villi. These cells have certain characters in common with malignant cells in that they are rapidly growing, and infiltrate the decidua and, in some cases, other tissues. The administration of certain of the heavy metals has long been known to produce abortion. Their action on pregnant does has been investigated at Liverpool, and it is claimed that lead has a specific action on the syncytium, causing necrosis and thus giving rise to abortion. Other metals, including copper, act in a different way—namely, by producing haemorrhage.

The analogy between new growth and chorion has given rise to the suggestion that lead might have a specific action on new growth. Subsequent investigations tend to confirm this, both from clinical experience and from the various chemical and pharmacological investigations, which show, *inter alia*, that after this treatment the new growth has a high lead content.

### Technique.

The lead is introduced intravenously in the form of a coarse colloid suspension containing 0.5 per cent. of lead. In this form it has no immediate poisonous effect, and considerable quantities can therefore be introduced with safety. The lead becomes fixed in the various tissues; it is suggested that it acts by its gradual ionization, and that the most poisonous effects occur in those tissues where it has been fixed in largest quantities. This, while accounting for the necrosis in the new growth, is probably also the cause of the damage which may be produced in the liver, kidneys, blood, and certain other organs; and therefore before commencing treatment it is necessary to ascertain that these organs are not already the seat of any gross lesion.

### Contraindications.

The more important contraindications are hepatic insufficiency, renal disease, advanced morbus cordis, marked anaemia, and wasting. Extensive preliminary investigations, chiefly of a pathological nature, are therefore carried out with a view to passing the patient as fit for treatment.

### The Course of Treatment.

The treatment is spread over four or five months; ten or twelve doses are usually given, and the total quantity of suspension injected is 120 c.cm.—that is to say, 0.6 gram of lead.

In the course of treatment the patient suffers to a greater or less degree from lead poisoning, and in some cases this effect is so severe that it may be necessary that it should be controlled by the intravenous administration of calcium chloride. Much useful experimental work has been directed to a better knowledge of lead poisoning, which in itself is a matter of great importance, quite apart from the question of malignant disease. It is remarkable that, a few months after the treatment is finished, the patients lose all signs of the effects of lead, and look particularly robust and healthy.

### RESULTS.

It is as yet too early to judge the results of treatment by statistical methods, but when the cases are critically examined it becomes evident that they must be divided into two groups:

1. Those in which the growth has been treated by lead and by no other means.
2. Those which have been treated by lead, and in addition by surgery or irradiation, or both.

It is obvious that only those cases which have been treated by lead alone are of real importance. The second class of case—namely, that in which other treatments have been employed, whilst clinically of great significance, are not of such value from a scientific point of view. For example, it is within the experience of most surgeons that from time to time when an avowedly incomplete operation is performed, the patient yet remains apparently well for a considerable time before there is any recurrence of signs.

### CONCLUSIONS.

Remarkable and impressive as are certain of the cases in which lead alone has been used, it cannot be too emphatically stated that the importance of the research being carried out at Liverpool lies, not in the wonderful individual results obtained (which form only a small percentage of the cases treated), but in the fact that it is the first time in history that a generalized treatment has been found that brings about a local disappearance of a cancerous growth.

From a scientific point of view malignant disease differs from any other disease in that control cases are not required, the chances of the spontaneous disappearance of a malignant tumour being negligible. If, therefore, with any given treatment really malignant tumours do disappear then it may be regarded as certain that it is due to the treatment given. The necessity for further investigation into the exact action of the lead cannot therefore be too strongly advocated. In the case of radical surgical operation, or the use of the actual cautery, the principle involved is simple—namely, that of removing all the malignant cells so that none remain behind to grow; but in the case of lead and of radiotherapy the exact sequence of events leading to the disappearance of the growth is but little understood. The scientific worker is buoyed up with hope that the solution of this problem will lead to discovery of the fundamental principles which, when embodied in some form of treatment (whether akin or otherwise), will with reasonable certainty cause the disappearance of every malignant cell, and thus go far beyond the limitations of surgery.

At no other period in the history of medicine has so much attention been paid to the investigation of malignant disease as at the present time. The public expect a specific cure to be found, and the press is on the tiptoe of expectation. They do not understand that scientific discoveries are evolved little by little, and unfortunately, moreover, their anxiety that this goal should be reached

makes them exaggerate the importance of any new work. The workers themselves are appalled at times to find that some purely scientific statement has been taken up and so turned and twisted as to suggest that a panacea has been evolved. By none is this more keenly felt than by Professor Blair Bell and his co-workers, who have never claimed that lead treatment is an infallible cure for malignant disease, but they have approached the matter from a scientific standpoint, a fact which is evident to all who visit Liverpool.

## NERVOUS AFFECTIONS OF THE OESOPHAGUS.

SEMON LECTURE BY DR. A. BROWN KELLY.

The Semon Lecture under the auspices of the University of London was delivered in the Robert Barnes Hall at 1, Wimpole Street, on December 2nd, by Dr. A. BROWN KELLY of Glasgow, who took for his subject "Nervous affections of the oesophagus." The chair was occupied by Dr. ANDREW WYLIE, President of the Laryngological Section of the Royal Society of Medicine.

Dr. BROWN KELLY said that he intended to deal mainly with spasm of the upper and of the lower end of the oesophagus, and only very briefly with paralysis. He first gave a close description of the structure and function of the oesophagus, and remarked how little was known—and that mainly of a negative character—about the influence of the sympathetic system on the gullet. With regard to spasm of the upper end of the oesophagus, he uttered a warning against the passage of bougies blindly before endoscopic examination had been made. In some cases, when spasm had been present for years, malignant disease supervened, and if in such cases a bougie was inserted with the force necessary to overcome the spasm fatal damage might be caused. The patient should be placed under a general anaesthetic, and a thorough examination made. The treatment of this affection consisted in stretching the muscle; the immediate benefit of stretching was that the patient was able comfortably to swallow food which for years he or she had been unable to take. It was important to convince the patient of his new power of deglutition, and he should be required before leaving hospital to eat a variety of foods hitherto impossible. The lecturer thought that the relation of pharyngo-oesophageal spasm to anaemia would be a fruitful subject for investigation. This association, though recognized by endoscopists, had not been placed on a scientific basis.

Turning next to spasm of the lower end of the thorax, which occupied the main portion of his lecture, Dr. Brown Kelly pointed out that it was in the hiatal region that cardiac spasm was seen. Spasm at the lower end of the oesophagus differed essentially from that at the entrance of the canal owing to dissimilar conditions in the two situations. The muscle, which at the upper end was striated and strong, was at the lower end unstriated and yielding. The upper end was closed except during deglutition, while the lower end expanded and contracted with the movement of the chest. The onset of the disease was insidious and excited little attention, so that the patient, when first seen by the doctor, might have a history of an affection extending back for months or years. His complaint was of occasional difficulty in swallowing and pain in the lower chest. As the symptoms caused only temporary discomfort they might be borne for a long period before advice was sought, but gradually they became more pronounced and the patient became unable to take a meal without obstruction and regurgitation. In the absence of appropriate treatment, death from starvation might terminate one of the periods of enforced fasting. The lecturer exhibited a chart showing in the case of one patient that in the course of four meals in one day he had swallowed 116 oz. of food, of which he had regurgitated 69 oz. and retained only 47.

He next described the method of making the x-ray examination in such cases, and mentioned the interesting investigation by the cinematograph of the part played by the oesophagus during deglutition as revealed by x rays. The appearance of the dilated oesophagus in cardiospasm was usually fairly uniformly sausage-shaped. Mottling or

fuzziness was often seen in the upper part owing to the presence of air, and an irregularity at the deepest part might be due to retained food. Sometimes the oesophagus was spindle-shaped. Dilatation of the oesophagus was met with in other obstructive diseases, but in none did it attain such great dimensions as in cardiospasm. In cancer, cicatricial stricture, and compression stenosis the dilatation was not comparable with that met with in this condition.

For endoscopic examination the patient should be placed under a general anaesthetic which permitted a thorough inspection of the oesophagus. In introducing the oesophagoscope rather more resistance was met with than in the normal subject. When the oesophagus was entered a large quantity of cloudy fluid rushed along the tube and could be drained off. At the lower end soft masses of food were usually collected. Besides dilatation the oesophagus would be found to have undergone elongation. The average length of the oesophagus from the upper teeth was 40 and 39 cm. in men and women respectively, but in a series of cases of spasm it was found elongated by an average of about 3 cm., without taking into account the fact that the average stature of the group of patients taken was rather below the normal. Heightened reflex activity at the hiatus was looked for in 18 patients with cardiospasm, and found in 17 of them, whereas in patients with affections of the oesophagus other than cardiospasm it was absent in all. This was, therefore, an important sign of cardiospasm. The patient himself could do much to assist in controlling this disturbance, especially by his choice of food, and by the care he exercised in swallowing it. All food must be thoroughly masticated and swallowed with an effort. Several efforts at deglutition might be necessary before it was accomplished, and the presence of a stranger at table, especially if he appeared to the patient to be watching him, might frustrate the act. Similarly, a faulty position of the body might hinder the accomplishment. Some patients felt compelled to eat their meals standing up. Sedatives were not called for in treatment. The passage of bougies assisted deglutition at once, but the improvement as a rule quickly passed off. The surgeon should aim at stretching the cardia to a greater degree than could be attained by the largest bougies, and he gave an illustrated description of an apparatus whereby a rubber pack which could be distended with water was used for this purpose.

The lecturer concluded with some account of a toxic variety of spasm as observed by him in two victims of "botulism" whom he had the opportunity of examining during the food poisoning outbreak in Scotland in 1922, when, as a result of eating some sandwiches, eight persons died of this condition. There was palsy of the ocular muscles and gradual involvement of the throat, larynx, and tongue. The toxic effects were apparently limited to the motor neurons, for intelligence was preserved until the end. He understood that this outbreak was the first of its kind in this country, and that there had been none since.

## RADIUM THERAPY.

REPORTS FROM RESEARCH CENTRES.

THE Medical Research Council is entrusted by the Government with a stock of radium salt for distribution to suitable institutions, and a summary of reports from these centres is published annually; that for 1925<sup>1</sup> has just been received. In the JOURNAL of December 20th, 1924 (p. 1170), we dealt with the report for 1923, and in our issue of April 24th, 1926 (p. 747) we referred at length to the report for 1924. The present report contains a summary of results from nine clinical centres: the Middlesex Hospital, University College Hospital, St. Bartholomew's Hospital, King's College Hospital, the London Hospital, St. Peter's Hospital, Birmingham General Hospital, Cardiff Royal Infirmary, and Aberdeen Royal Infirmary. In addition to these the London Association of the Medical Women's Federation receives radium for use in a group of hospitals; reference to its work appears at page 1132 of this issue. Radium salt is also allocated to the Irish

<sup>1</sup> Medical Research Council, Special Report Series, No. 112. Medical Uses of Radium: Summary of Reports from Research Centres for 1925. London: H.M. Stationery Office, 1926. Price 1s. 3d. net.

Public Health Council, Dublin, for distribution in Ireland. No reference is made to the treatment of rodent ulcer or to non-malignant conditions, but in the introduction it is mentioned that in the first case the suitable lines of procedure are generally known, and the technique for added that radium has been shown to be valuable therapeutically in myeloid and lymphoid leukaemia, though the benefit is only temporary as a rule. No radical change has been made in the radium therapy of malignant disease during the last five years, but there is now a tendency to use numerous comparatively small sources of radium for long intervals (for seven to ten days) in place of applying single intense sources for shorter times.

#### Clinical Investigations.

The investigations considered in the report are classified under six headings—namely, cancer of the breast; cancer of the uterus; carcinoma of the mouth, nasopharynx, larynx, and oesophagus; carcinoma of the rectum, bladder, and prostate; sarcoma and lymphosarcoma; and experimental investigations.

1. Cancer of the breast was treated by surgical radium therapy at the Middlesex Hospital. Of fourteen cases of recurrent carcinoma in this situation a radical operation had been performed in eleven, and in the remaining three there had been local removal before commencing radium treatment. It was found that in advanced cases without hope of cure treatment by radium would prevent ulceration of the recurrence, and so save the patient from very much pain. In earlier cases large doses often caused the tumour to disappear or retarded its growth. At St. Bartholomew's Hospital eight primary breast tumours and eight recurrent primary carcinoma of the ordinary type with a small growth are very encouraging. Apparent cure followed in three cases out of eight, and the remainder showed good local results. In recurrent carcinoma the results of treatment were extremely bad, and in no case was life appreciably prolonged. From Dublin reports were received upon four cases of recurrence after operation, one case in which radium was associated with operative treatment, and four inoperable cases. Judicious radium applications were found to give effective assistance to subsequent surgical work. Surface radium therapy of carcinoma of the breast was used at the Middlesex Hospital for primary breast cases, for inoperable supraclavicular recurrences, and for nodular recurrences. It is noted that in many cases the existence of a second nodule is evidence, not of a localized, but of a wide-spread condition, and that therefore radium treatment often fails to benefit the patient, though the actual nodules dealt with may disappear.

2. Cancer of the uterus is considered mainly from the point of view of technique rather than of statistics, and the reports from ten centres show that there was much variation in the procedure adopted and the dose. The introduction of 50 to 100 mg. of radium element into the cervical canal for twenty-two to twenty-four hours was used by all except St. Bartholomew's Hospital, where a study of the effect of much smaller quantities acting continuously for six days is in progress. For tumours which could not be reached by radium tubes in the cervical canal the procedure differed considerably. In some cases applicators were packed round the tissues involved; in others needles were inserted into the growth. Statistical data were received from University College Hospital, Birmingham General Hospital, Cardiff Royal Infirmary, St. Bartholomew's Hospital, and Dublin. By collating the data it is shown that of 178 patients with inoperable disease reported not less than one year after treatment, 120 had died, 27 were apparently free from the disease, and 31 were alive but not cured. Of 16 border-line or operable cases, and 6 were alive but not free from the disease. Reports on cancer of the body of the uterus were received from Cardiff (11 cases), from the Medical Women's Federation (6 cases), and from Dublin (1 case).

3. Carcinoma of the mouth is the subject of reports from St. Bartholomew's Hospital, Middlesex Hospital, Birmingham, Aberdeen, and Dublin. At King's College Hospital ten cases of cancer of the oesophagus were treated with

immediate benefit as far as pain and swallowing were concerned. After a few days there was usually some return of the symptoms in consequence of inflammatory reaction. The growth occasionally became less vascular and appeared firmer and denser, but actual fibrosis and arrest were not obtained. Birmingham reported good results of the combination of diathermy and radium, while in Dublin three cases were treated with combined local and surface application with temporarily good results.

4. Carcinoma of the rectum was treated by radium in four cases at St. Bartholomew's Hospital, in eight cases at King's College Hospital, two cases at Aberdeen, four in Dublin, and one at Cardiff. St. Peter's Hospital, London, reported upon the treatment of two cases of carcinoma of the bladder and one of the prostate. Cardiff and Dublin returned one case each of carcinoma of the bladder.

5. Sarcoma of bone was treated with success in two cases at the Middlesex Hospital which prior to the introduction of radium therapy would have been considered almost hopeless. Both patients are alive and apparently free from growth more than eighteen months after the first appearance of the growth. Aberdeen reported the treatment of two cases of sarcoma, St. Bartholomew's Hospital three, Cardiff five, King's College Hospital one, and Birmingham and the London Hospital two each. Included in these reports were four cases of spindle-celled sarcomata, with good results in three and a questionable result in one case; three round-celled sarcomata, with success in one case; failure in two cases; one lympho-sarcoma, and one and osteo-sarcoma which ended favourably.

6. Experimental work was continued at the Radium Institute, and two investigations were published in 1925. The first, in the *British Journal of Experimental Pathology*, dealt with the artificial cultivation of tissues with reference to the production of cancer by means of radium and  $\alpha$  rays; the second investigation, entitled "The reaction of the skin to a radium exposure repeated after varying lengths of time," was published in the *British Journal of Radiology*. In the first case it was shown that extracts of normal tissues inhibited the growth of normal cells cultivated *in vitro*, and that the exposure to radium or  $\alpha$  rays of normal tissues, either *in vitro* or *in vivo*, destroyed the inhibiting factor, thus suggesting that cancer might be the result of the destruction of growth-inhibiting factors. The second investigation indicated that a certain small extent of skin desensitization could be obtained by administering a small dose of radiation. Dr. J. C. Mottram communicated to the Royal Society a paper upon the effects of beta rays upon the growth and division of tumour cells. Radium salt was also supplied to Sir Ernest Rutherford at the Cavendish Laboratory, Cambridge, for purely experimental work.

#### CONFERENCE ON MENTAL WELFARE.

A CONFERENCE, called by the Central Association of Mental Welfare, was held at Westminster on December 2nd and 3rd. The subjects discussed were the after-effects of encephalitis lethargica, borderline cases and delinquency, the training of teachers for special schools, and the care of defectives outside institutions. The large majority of those present being lay people it was, of course, the social and administrative side of mental deficiency rather than the medical side which was discussed.

#### Lethargic Encephalitis.

Sir ARCHIBALD BODKIN, director of public prosecutions, who presided over the session which discussed encephalitis lethargica, referred to the interesting report on the cases in Sheffield, the result of the investigation prompted by the Sheffield Division of the British Medical Association (*JOURNAL*, November 27th, p. 1008), and hoped that more appropriate, perhaps more humane, treatment for this class of offender would be the result of the bill recently introduced into the House of Commons.

Dr. A. F. TREGOLD raised the question whether the mental sequelae of encephalitis lethargica were temporary or permanent. He had seen cases in which both serious intellectual impairment and marked conduct disorder had,

in the course of time, undergone very great improvement; on the other hand, there were cases which, even after a lapse of three or four years, showed no appreciable change. One of the obstacles to treatment was a narrow interpretation of the clause in the Mental Deficiency Act whereby, to permit of certification for institutions under that Act, the defect must have been present from birth or from an early age. He himself thought an "early age" might include up to 16, but others took a much narrower view. At present there was no adequate provision for these children, in spite of the fact that they were numerous and constituted a severe social menace. The best solution would be the foundation of special establishments under medical supervision.

Dr. F. C. SHRUBSALL said that the Metropolitan Asylums Board had opened one such institution, but the period had been too short to permit of any definite deductions; the experiment had shown, however, that two types of cases presented special difficulty—namely, mentally deranged and violent cases, and those showing symptoms of Parkinsonism. The latter might ultimately require to be dealt with at some home for incurables, and the former placed under prolonged and possibly permanent care in a mental hospital or certified institution.

Dr. E. MAPOTHER said that a great deal still remained to be done in the investigation of Parkinsonism and of the analogous mental "stiffness." The difficulty of the situation arose from the obscurity of onset of encephalitis. He was inclined to make the time interval between the onset of the disease and the mental after-effects even longer than the two years which Dr. Tredgold had suggested. The provision of special institutions would not solve the question. He favoured the appropriate use of existing arrangements. It would be impossible to provide in numerous localities all the specialized kinds of institution which cases of encephalitis lethargica might need, and any institution for all the sequelae would be of the most heterogeneous description. What was needed for these cases was what was required for mental cases generally—namely, some institutions for early treatment without certification. He commented on the refusal of magistrates to grant detention orders in cases of conduct impairment, though they were ready enough to do this in cases which exhibited hallucination and delusion, which the post-encephalitic did not show. He thought every first offender should be seen by a doctor.

#### *Borderland Cases.*

In the discussion on borderland cases Dr. W. R. K. WATSON, senior medical officer to Brixton Prison, estimated the number of subnormals at 3 per cent. of the general population and 5 per cent. of the prison population. Many subnormals, of course, were not delinquent at all, but were of the most harmless and amiable character. The subnormals in prison were unfit for ordinary prison discipline, and were not exposed to it. They were regarded as medical cases and located in hospital or in a reserved part of the gaol, and their treatment approached as closely as conditions permitted to that given in a mental hospital. He advocated a certain specialization in function in prisons, with the setting apart of one or more prisons for borderland delinquents, with medical staffs selected for their knowledge of and interest in mental work. Dr. E. GOODALL (Cardiff Mental Hospital) gave some account of the out-patient clinic which was started at the Cardiff Royal Infirmary six years ago for dealing with patients who, though certifiable, need not and should not be certified. Its work had been not without result as an object lesson, for the Poor Law authorities, in drawing up plans for an important hospital near the city, had made provision for the indoor treatment of early psychoses and psycho-neuroses in the shape of a separate building on the estate. He was opposed to outdoor clinics in psychiatry unless indoor clinics were associated with them.

#### *Teachers for Special Schools.*

At the session which dealt with the training of teachers for special schools, over which Dr. H. B. BRACKENBURY presided, Lord EUSTACE PERCY, President of the Board of Education, described this as the most difficult problem to be faced in education, in view of the wide and varied range of mental defect.

## England and Wales.

### LONDON SCHOOL OF MEDICINE FOR WOMEN.

THE annual dinner of the London (Royal Free Hospital) School of Medicine for Women was held at the Savoy Hotel on December 2nd, when Lady Barrett, dean of the school, presided over a company of nearly four hundred. Sir John Rose Bradford, P.R.C.P., proposed the toast of the evening, and spoke of the school as having a very creditable past and a very ambitious future. He remarked that medical schools, if they were to fulfil their high functions, must be not only centres of training but of research. With regard to the hospital, he rejoiced that the voluntary principle appeared now to be more firmly established in this country than it had been for many years past. Voluntaryism in hospitals signified more than the obtaining of voluntary funds from the public; it stood for disinterested and voluntary service of various kinds, and in this respect the Royal Free Hospital had been exceptionally fortunate. Lady Barrett, in responding, referred to the fact that at the previous dinner those present had received from their late beloved dean (Dame Aldrich Blake) what proved to be her last message. After referring to the approaching completion of the new children's ward, to be opened by the Queen early next year, and to the approaching centenary of the hospital, she said that a few years ago large numbers of students who had qualified were applying for and obtaining posts in the public health services, but later there came what she described as a most extraordinary and un-British regulation forbidding the occupancy of such posts by married women. Every normal young woman wished to marry, and the regulation was regarded as a restriction on liberty; but it had had the effect of bringing about a great change in the kind of work undertaken by those graduating. They were now, to a much larger extent than formerly, entering general practice, and there was no sphere of work in which women were more likely to come into their own, for in general practice one of the first duties was preventive medicine. Women in general practice would assist in clinical research into the origins of disease. Moreover, with the increase of cottage hospitals and public laboratories, the life of the general practitioner was likely to be more full of interest than hitherto. The toast of "The Guests" was proposed by Mr. Ulysses Williams in a very amusing speech, and responded to by Dr. Franklin Sibly, who said that the University of London would shortly have to take in hand the very serious task of co-ordinating the work of the colleges and schools from the point of view of organizing a much larger measure of post-graduate medical study. He was sure that in that enterprise the Royal Free Hospital and School of Medicine would play its due part. The health of the Chairman was proposed by Dr. Mary Blair.

### THE HOSPITAL SAVING ASSOCIATION.

The Hospital Saving Association seems to be establishing itself in a strong position. The object of the association is to enable persons of small means to make provision for hospital treatment for themselves or their dependants, if it should become necessary. The provision is made by means of small weekly contributions collected from groups of contributors in many different occupations; and from the fund so gathered distribution is made to hospitals, whether co-operating in the scheme, non-co-operating, or rate-aided, in accordance with the number of contributors treated and the duration of their stay in hospital. About a thousand representatives, chiefly group secretaries, met in the Kingsway Hall, London, on December 1st, to receive from Viscount Hambleden the annual report of the association, and to listen to an address by Lord Dawson of Penn. Lord Hambleden stated that the number of contributors to the scheme was 267,000, representing with their dependants about three-quarters of a million persons for whom hospital treatment could be provided. With the final distribution to co-operating hospitals recommended by the executive council, the total payments for the year made to hospitals and other institutions amounted to over
